HEATING MANTLES

PATENTED

The Electrothermal Heating Mantle illustrated is one of a special series (MJ), light weight, completely flexible, highly elastic, fitting snugly round the flask whether flat or round bottomed. The ingenious elastic neck opening enables the mantle to be fitted as the final item in the installation. Standard types available for use with beakers, funnels and stills; modified designs are produced with bottom or side outlets.

Is your laboratory heating equipment as up to date as it could be? How far is it efficient for its purpose, thoroughly safe and economical in operation? In other words, have you installed Electrothermal laboratory heating equipment, most advanced apparatus of its kind produced? Electrothermal standard heating equipment is stocked by all laboratory suppliers and carries a 12 months' guarantee. Special designs produced to specifications.

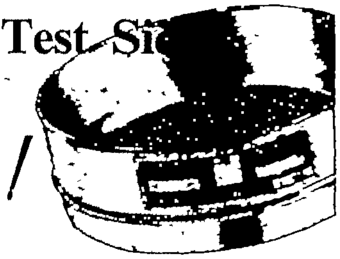
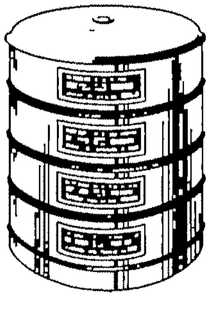
ENDECOTT'S

Standard Test Si



for Accuracy!

To B.S.S. or American Standards



Accurate sampling or testing is essential and Endecott's Test Sieves are *guaranteed* to conform to specification. The patent sieve body contains no crevices or blind-spots to impair test efficiency. Durability is assured by attachment of the wirecloth direct to sieve frame, giving uniform tautness and long life. Standard sizes are available *from stock*, special requirements can be satisfied promptly.

X Obtainable from all first class Laboratory Furnishers. Write for literature. X

Ready July

Gas Turbine Power

G. M. DUSINBERRE

A complete treatise for the engineer written from the fundamental viewpoint of the mechanical specialist. Contents include:—thermodynamics, basic turbine cycle, variations on basic cycle, gas flow, compressors, combustion, heat transfer, and many miscellaneous topics.

38s. net

Steam Power Plants

ZERBAN and NYE

A uniquely readable and up-to-date treatment of the elements of steam power generation. Running as a thread throughout the book is an analysis of power plant economics, so often the deciding factor in engineering operations.

Illustrated. 52s. 6d. net

Seismic Prospecting for Oil

C. HEWITT DIX

A complete summary of the most up-to-date methods in geophysical prospecting. Special consideration is given to the interpretation of reflection seismic data and refraction seismic work.

HAMISH HAMILTON IMPORTATIONS

90 Great Russell Street, London, W.C.1

TWO IMPORTANT BOOKS ON THE THEORY OF STATISTICS

THE ADVANCED THEORY OF STATISTICS

M. G. Kendall, Sc.D.

The two volumes of this book—in their subject among the most important published in recent years—provide a thorough and masterly exposition of the theory of statistics as it now exists. To achieve clarity the author has necessarily adopted a rather advanced mathematical treatment, but he has not let the mathematics get out of hand. Broadly, Volume I deals with frequency distributions, probability, sampling and sampling distributions, the chi-squared distribution, and the theory of correlation. Volume II is concerned with estimation, regression, analyses of variance, tests of significance, multivariate analyses, statistical inference, and time series

Vol. I. 5th edition. 475 pp. (10¼ in. × 7¼ in.) Price 52s. net

Vol. II. 3rd edition. 521 pp. (10¼ in. × 7¼ in.) Price 60s. net

AN INTRODUCTION TO THE THEORY OF STATISTICS

G. U. Yule, F.R.S., and M. G. Kendall, Sc.D.

This well-known text, revised by Professor M. G. Kendall, is designed for students of the many sciences in which statistical methods are employed. It provides a complete introductory course in statistics, and includes some important tables for reference. Many worked examples are given, and there are numerous exercises for the student to solve for himself—with hints and answers at the end of the book.

UNIVERSITY EDUCATION IN CENTRAL AFRICA

IN 1938 a Royal Commission under Lord Bledisloe's chairmanship considered the question of closer association between the Central African territories of Southern Rhodesia, Northern Rhodesia and Nyasaland and recommended the setting up of an inter-territorial Council, charged with co-ordinating the existing Government services and with surveying the plans for development in the whole area. Because of the War, the recommendations of this Commission could not be acted upon immediately; but in 1945 the Central African Council was established with the object of promoting the closest possible contact and co-ordination of policy and action between the three territories in all matters of common interest. In 1949 the Central African Council appointed a special committee under the chairmanship of Sir Harold Cartmel-Robinson to consider the need for facilities for higher education for Africans in Central Africa. The report of this special committee, presented in November 1949, recommended that such facilities should be made available and that a Commission should be appointed to advise in detail on the steps needed to implement its recommendation. No action was taken at that time on this or any other recommendation in the report of this committee.

In 1950, the Government of the Union of South Africa decreed that because the educational facilities of the indigenous population within the Union were inadequate, native students from territories outside the Union would no longer be admitted to educational institutions in the Union after the end of 1953. The Central African Council then asked the Special Committee on Higher Education for Africans (the Cartmel-Robinson Committee) to reopen its inquiries. The Committee revised its earlier report, and in April 1951 again recommended that a Commission be appointed to consider the situation. In September 1952 a Commission was appointed, under the chairmanship of Sir Alexander Carr-Saunders, to report to the Central African Council on the general question of higher education for Africans in Central Africa, and in particular to make proposals concerning a college for Africans in the Central African territories; the Commission has recently published its report*.

The Commission urges in this report that a university college should be founded without delay, and that it should be worthy to take its place by the side of those instituted with such success in the past decade in East Africa and the West Indies, Nigeria and the Gold Coast. The need for such a college is clear. There is a sufficient and increasing output from the secondary schools of the three territories, and the college would almost certainly attract students from the High Commission territories (Bechuanaland, Basutoland, Swaziland) as well as from Belgian and Portuguese territories, and even from the Union of South Africa. The Commission forecasts that if the minimum entrance standard were a good performance in the Cambridge Overseas School Certificate Examination, the college might expect to admit a hundred Africans a year in 1957; thereafter the number should increase substantially. For university-educated Africans there are many openings, and these will increase with time. The Commission accepts the view laid down in the Asquith report (Cmd. 6647. H.M.S.O., June 1945), which, in discussing the general question of university education in the Colonies, states: "In our view it is essential that Colonial Universities should be autonomous, in the sense in which the Universities of Great Britain are autonomous. . . . The Colonial Universities should, in effect, have full freedom to manage their own affairs". Nevertheless, as a first step it is suggested that the college to be instituted should enter into special relationship with the University of London; this would permit concessions in the standard of entrance, but would ensure that there was no lowering of the degree standard. It would therefore be expected that an average student would spend four years within the walls of the college. But this should be only the first step in the founding of a full and autonomous university, and the university must be so sited that it could expand to a size and stature adequate for all the future university needs of Central Africa. The Commission therefore recommends that a site should be at least two square miles (1,280 acres) in area, and that the college should be established by Royal Charter, a step which would guarantee both autonomy and provision for steady growth. The usual departments in arts and sciences should be instituted at the start, and the academic staff at the end of the first five-year period is estimated at seventy-two. The Commission attaches great importance to the development of research work and to the need for a good library.

---

* Report of the Commission on Higher Education for Africans in Central Africa. Pp. iv+94. (London: Crown Agents for the Colonies, Millbank, S.W.1.) 5s.

The report most significantly recommends that the university college to be established in Central Africa should be multi-racial. It states: "It is contrary to University tradition to have regard to race, religion or class when selecting candidates for admission".

In discussing where the multi-racial university college could be situated, the Commission states its view that Salisbury, Southern Rhodesia, should if possible be the centre to which the college be related. But the task of the Commission was complicated by the existence of a scheme sponsored by the legislature of Southern Rhodesia for the founding of a Rhodesian University. The decision to institute such a university was taken in 1946 when the Legislative Assembly of Southern Rhodesia resolved that as soon as practicable a Rhodesian University should be established to serve the two Rhodesias and neighbouring territories, and in 1947 the governor of Southern Rhodesia established a Rhodesian University Foundation Fund and appointed trustees. In 1952 the Legislative Assembly of Southern Rhodesia passed an Act entitled "The University Charter and Inaugural Board (Private) Act", by which an inaugural board was set up. The trustees of the Rhodesian University Foundation Fund state that they have received gifts of something like £300,000, and the city of Salisbury has given a site of 250 acres for the proposed university. Queen Elizabeth the Queen Mother is laying the foundation stone of the first building during her visit to Southern Rhodesia. The Carr-Saunders Commission pays warm tribute to those responsible for this imaginative and public-spirited act on the part of the settlers in Southern Rhodesia, and welcomes the Rhodesian University as a basis of the proposed Central African University, provided its sponsors incorporate in their plans the elements which it deems essential, namely: (1) that it should be multi-racial; (2) that it should be autonomous; and (3) that it should be capable of expansion to the desirable extent by being placed on a site of at least 1,280 acres.

The Cartmel-Robinson Committee had discussed the relationship of the university college proposed for the higher education of Africans and the Rhodesian University, and had suggested the possibility that both these institutions be sited in or near Salisbury, and that there should be a link between them. This proposal the Carr-Saunders report rejects for a number of reasons, but particularly because the Rhodesian University would not be autonomous, because the proposal could clearly lead to racial segregation, and because the dissipation of resources between the two colleges would fail absolutely to bring into being a university worthy of Central Africa. The Carr-Saunders Commission is not unanimous on this point, since one of its members, Dr. Alexander Kerr, formerly principal of the South Africa Native College at Fort Hare, states in a note of reservation that "nothing in the past history of these or neighbouring Territories justifies the expectation that an inter-racial policy of admission would be allowed to proceed to the point when the numbers of the respective races would approximate to equality, and still less to the stage where the African element will exceed the European". Dr. Kerr therefore favours the immediate foundation, independently of the proposals for the institution of the Rhodesian University, of a university college for African higher education at Lusaka in Northern Rhodesia.

Since the Carr-Saunders report was published in May, the inaugural board of the Rhodesian University has declared that its University would be inter-racial and that admission will be solely dependent on educational attainments and the good character of students. The inaugural board, however, considers that the site of 250 acres already acquired within the city of Salisbury is a good one, and it doubts whether an alternative area of 1,250 acres could be found near Salisbury, and whether a modern university could afford to place itself far from existing centres of civilization. The Board is reported to have said that "to start afresh on a new site and with an entirely new Charter would be needlessly to torpedo all that has been built up".

The Carr-Saunders report is explicit on the need for a site other than that of 250 acres already acquired for the Rhodesian University. This site is in a built-up European residential area of Salisbury, and even if it were large enough for the first stage in the history of a college, it allows no room for the expansion which will undoubtedly be needed by, say, fifty years hence. Furthermore, "An inter-racial institution would be an experiment in Central Africa, and to try it out in a European residential area would not give it the best chance of success".

Also, the statutory dependence of the Rhodesian University on the Southern Rhodesian Government (even if in time this dependence passes to the Federal Government) is not compatible with the absolute autonomy regarded by the report as essential.

The Carr-Saunders report recommends that a capital sum of £1¼ million should be acquired for the institution of the proposed university college, and that application should be made to the Colonial Development and Welfare Fund for this sum. The report, as Lord Hemingford said in a recent article in *The Times Educational Supplement*, is a challenge to the United Kingdom. The acceptance of this challenge would mean that H.M. Government would at once make clear its willingness to provide this capital sum. Indeed, the suggestion has been made that the British Government might go farther than the Commission's proposals and not only set the college going but also endow it during a preliminary stage of complete independence. It has been estimated that this would cost £5 million.

It will be disastrous for capital and energy to be dissipated in Central Africa by an attempt to found two separate universities. It would be equally undesirable that the Rhodesian University should curtail in advance its hopes of expansion because of an insufficiency of both land and capital finance. A firm statement now by the British Government of the conditions under which it would provide financial support for a university college in Central Africa would clarify the position at once for all concerned, and particularly for the sponsors of the Rhodesian University scheme, who might consider associating themselves with the far more ambitious plan put forward in the Carr-Saunders report.

It is only too easy for the British Government to find reasons for procrastination under present conditions. It is perhaps unfortunate that one of the territories concerned, namely, Southern Rhodesia, a self-governing colony, is administratively associated with the Commonwealth Relations Office in London, whereas Northern Rhodesia and Nyasaland—both protectorates—come under the Colonial Office; it is not difficult to see that these two Government offices may fail to come to agreement concerning responsibility for a capital grant. Moreover, the Carr-Saunders Commission reported to the Central African Council and not to the British Government. However, there should be no insuperable difficulty in preparing a joint statement on behalf of the Commonwealth Relations Office and the Colonial Office. If this can happen—and happen quickly—it can do more than anything else to ensure the success of a great educational step forward in Central Africa, and to make clear to indigenous peoples in those territories that partnership in one important sphere of civilized existence is soon to become a reality.

JORDAN'S COSMOLOGY

Schwerkraft und Weltall

Grundlagen der theoretischen Kosmologie. Von Pascual Jordan. (Die Wissenschaft, Band 107.) Pp. viii+207. (Braunschweig: Friedr. Vieweg und Sohn, 1952.) 15.80 D. marks.

PROF. PASCUAL JORDAN collaborated with Profs. M. Born and W. Heisenberg in the invention of matrix mechanics; then he became noted for his work on unified field theories, and more recently he has been one of the first to introduce the notion of continuing creation into present-day cosmological theory. The many to whom his name has thus become familiar are bound to be interested to know what his new book is about.

Its subject is described in the sub-title as the "foundations of theoretical cosmology". But it is divided into Book 1 on the Riemann–Einstein theory and Book 2 on extended gravitational theory; there really are two books.

The first is a self-contained account of Riemannian geometry and general relativity. Prof. Jordan has bestowed great care upon its preparation, and he now hopes that it will serve as an introductory text for students. I think it has much to recommend it in this character and that it will convey a lively appreciation of the mathematical form and physical concepts of relativity theory. Some of the incidental features are of special interest, although their brevity leaves them somewhat inconclusive. Instances are § 18 on relativistic causality and some remarks in § 20 on Newtonian analogies (certain of which, however, I should regard as rather misleading).

The second 'book' is a presentation of Jordan's ideas on cosmology. There are several notions that have come to exercise a strong appeal to his mind. The first is that of the method of projective relativity; the second is that of the possible variability of the gravitational constant. This possibility was once briefly suggested and later discarded by Dirac; but it seems that Jordan found the original arguments more convincing than Dirac did, both on their own merits and also because their result corresponds to an apparently natural generalization in the mathematics of projective relativity. The third notion is that of the continual entry into the universe of fresh matter in the form of embryonic stars. This appeals to Jordan because he claims to relate it to an upper bound of possible stellar masses and to certain features of super-novæ. But also, if I have not misunderstood him, certain rather unsatisfactory quantitative features of cosmical models derived from his other ideas are in his opinion due to these being models of a smoothed-out universe. Evidently he regards his process of star-genesis as arising from his theory when this simplification is removed. However, he does not give a mathematical treatment of this process itself or show its mathematical connexion with the rest of the work (apart from presenting certain arguments that he thinks may make it mathematically plausible).

Prof. Jordan has already given some account of these ideas[1], and in his book he seeks to give them fresh coherence, though, as I have said, he does not succeed in finding a mathematical treatment that embraces them all; and he surveys astrophysical and geophysical evidence that he regards as favourable to them. Also, he seeks to meet certain criticisms, some of which are rather recondite. Actually, his ideas are vulnerable to much simpler objections; these have recently been summarized by H. Bondi[2].

Prof. Jordan has earned recognition as a pioneer in questioning previously accepted interpretations of the conservation laws of physics; but, so far as his specific suggestions are concerned, even the most sympathetic reader will recoil from the thought of the particular cosmic phenomena he mentions being manifestations of processes so utterly different from those required to account for apparently closely allied phenomena. If the reader is an astrophysicist he will know that these particular phenomena are in any event well on the way to explanation by current astrophysical theory.

It is the case that the subsequent but independent work of Bondi and T. Gold and of F. Hoyle also started from a reconsideration of conservation laws and also requires the notion of continuing creation. But the existence of these common features tends to be deceptive, rather than otherwise, in considering the respective contributions to cosmological thought. The merits of Jordan's suggestions can be judged on their own, but only after he has taken the trouble to explore their potentialities, as he has done in this book. While Jordan himself presents the work as a preliminary account of something worthy of further pursuit, the reader will almost certainly get the impression that the author is now fighting a rearguard action.

W. H. McCrea

MANUAL OF PAPER CHROMATOGRAPHY

Paper Chromatography

A Laboratory Manual. By Richard J. Block, Raymond LeStrange and Gunter Zweig. Pp. x+195. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1952.) 4.50 dollars.

Paper chromatography is now a standard technique in the laboratories of biologists, biochemists and chemists, and its considerable importance has been recognized by publication of two previous monographs[1,2] on the subject. This volume differs from its predecessors in being a laboratory manual, and as such it is a very welcome addition to the group.

The manual contains chapters on theory, general methods and quantitative methods, followed by chapters on applications in each of the major fields of biochemistry. The chapter on theory is very brief, as might be expected in a laboratory manual, and that on general methods is rather scrappily presented. The later chapters provide a fund of detailed information on specific applications with many comprehensive tables of R_F values. Much of this material is presented in a manner which makes reference to the original literature unnecessary. This is a valuable feature, as the original literature is so scattered.

Though the book contains a valuable fund of information, its presentation leaves something to be desired. The publishers claim, on the dust cover of the book, that its purpose is "the discussion and evaluation of the more important techniques developed in paper chromatography"; the most serious criticism of the book is that such discussion and evaluation are so frequently lacking. Though twenty-two solvents for the separation of amino-acids are described, their relative merits are not discussed; and, though five different methods of preparation of the ninhydrin reagent are given, the need for such variation is not mentioned. This lack of the critical approach may be bound up with the format of the book. The chapters are divided by very numerous and sometimes systematic subheadings. A fair degree of subdivision is essential in a book of this kind to assist in rapid location of specific information, and this is a useful aspect of the later chapters, but the method is here taken to excess and often leads to cumbersome treatment. A more discursive approach would frequently yield a more critical and informative text.

The manual covers the field of paper chromatography very comprehensively, but there are some unfortunate omissions. Most of the later sections of the book are well endowed with tables of R_F values; but those in the sections on amino-acids and sugars seem inadequate. Of twenty-two solvents described for the separation of amino-acids, R_F values are given for only three. It is a pity that there is no mention of partition chromatography in columns, which is such a useful adjunct to paper chromatography, especially where one is concerned with isolation or quantitative estimation of substances. There is also little mention of the valuable work on separation of peptides, or the fruitful marriage between paper chromatography and the isotopic tracer technique. There is a brief description of paper electrophoresis.

The book contains many useful illustrations, but Figs. 1 and 2 of Chapter 12 appear to have been interchanged, and the value of the two colour plates would be increased by fuller description of their contents. In association with Plate 1, a map of two-dimensional separation of amino-acids would be a useful addition. The apparatus illustrated in Figs. 5 and 6 of Chapter 3 could have been ascribed to Dent and co-workers, who first devised them[3,4].

In spite of these criticisms, which it is hoped will be taken in a constructive sense, the book will be of great value to anyone working in this field.

INTRODUCTION TO HUMAN PHYSIOLOGY

The Living Body

A Text in Human Physiology. By Prof. Charles Herbert Best and Prof. Norman Burke Taylor. Third edition. Pp. viii+792+16 plates. (New York: Henry Holt and Co.; London: Chapman and Hall, Ltd., 1952.) 37*s*. 6*d*. net.

This is an excellent book which could be used as an introduction to the subject of physiology by any type of student, and, after having mastered its contents, the larger kind of handbook should not be so overwhelming as it is sometimes said to be. The only objection to it appears to be in the nature of the first chapter, which gives a précis of the science of chemistry.

Now it is a truism that the start of any book is one of the most difficult of the hurdles which an author encounters on his course, and the awkward-ness of the start is enhanced when, as in the present instance, the book is itself an introduction to a complex subject. But it does not help a beginner if the first chapter is of the nature of a summary which is either superfluous or indigestible. If the beginner in physiology has no previous knowledge of chemistry, physics and biology, he had far better acquire some, because these disciplines provide tools and concepts without which modern physiology cannot be taught or understood. If the student has such background, then this introductory chapter is unnecessary and distracts from the main thread of the book.

But, apart from this quite minor objection—and it is a minor one because certainly few students are likely to use the chapter—the treatment goes along smoothly and competently. The contents of Chapter 2, which is a brief account of histology, are harmless enough but scarcely necessary if the student has done any general biology. The book seriously settles down to its real business with Chapter 3, on the blood, tissue fluids, etc., and there is no hitch in the story after that. It is clearly and accurately told, and with a modern point of view; the figures are numerous and clear; and stress is laid on aspects of the subject which are of practical importance, such as artificial respiration, shock, blood transfusion, and so on.

One of the difficulties in teaching physiology is that the body works as an integrated whole in which there is complex and continuous interplay between various component parts. Hence the orthodox treatment of the organism by systems is necessarily artificial. The control of function by the central nervous system, by the endocrine organs, and by collaboration between the two is most difficult to bring home at a first presentation. The present authors have tried to bring things together by cross-references as, for example, when dealing with the cardiac nerves by referring to chapters on the central nervous system farther on in the book. This is one way out of the difficulty, but in the end the only way seems to be for the student to read a physiology book twice or, better still, if he is intending to tackle the subject seriously, to read and digest such a book as this and then to pass on, with no terrors, to a more advanced book. In giving a clearly written and accurate book of an introductory kind, the authors have rendered real service to the teacher of physiology.

C. LOVATT EVANS

ANALYSIS OF PERSONALITY

The Scientific Study of Personality

By Dr. H. J. Eysenck. Pp. xiii+320. (London: Routledge and Kegan Paul, Ltd., 1952.) 30s. net.

THE extensive literature of experimental and speculative work on the topic of personality has indicated that the explanations of a person's behaviour present a particularly complex and intriguing problem. Both from an empirical and a methodological point of view, it is one of the most difficult problems ever to challenge scientific curiosity. The number of possible causes contributing to behaviour is large and varied and may involve reference to fields usually regarded as the province of the economist, historian, anthropologist, physiologist, neurologist, endocrinologist and geneticist. The problem is rendered even more difficult by the operation of the large number of offsetting influences which the individual encounters during his life; and the awkward fact for the exponent of correlational techniques is that experienced clinicians can disagree on the classification of the major abnormal states. Again, while reliable class differences may be established between normals, schizophrenics and psychotics in the performance of a particular task, the clinician is expected to understand the context of each patient's difficulties so that his recommendations as to therapy can be effective within their particular environment.

Dr. H. J. Eysenck begins by warning his reader against the 'prestige' value of the words 'science' and 'scientific' which may cloak questionable procedures; and then indicates that the scientific way of studying personality is to establish principles of classification by the methods of factorial analysis of correlations between the results of a variety of objective tests of behaviour. Although the suggestion of an *argumentum ad verecundiam* by appeal to the prestige of the methods vindicated in the physical sciences does arise, the operational definition of abnormal mental states by reference to the dimensions established by factorial analysis is lucidly presented. The author and his co-workers have undertaken a considerable amount of statistical labour, and some arresting correlations between test performance and clinical designations are reported. Although the discussion of these findings with reference to earlier work is not always marked by customary scientific humility, comparison with results based upon other populations will be awaited with interest.

The work is a competent exposition of techniques whereby tests indicative of abnormal states may be assessed and refined—an important and useful part of the objective approach in a difficult field. The problem as a whole, however, must surely involve a thorough analysis of environmental conditions associated with abnormal states and some indications as to therapy.

MODULATION THEORY IN RADIO COMMUNICATION

Harmonics, Sidebands and Transients in Communication Engineering

As Studied by the Fourier and Laplace Analyses. By C. Louis Cuccia. (McGraw-Hill Electrical and Electronic Engineering Series.) Pp. ix+465. (London: McGraw-Hill Publishing Co., Ltd., 1952.) 76s. 6d.

THE need to increase the speed of radio communication, to provide a wide range of services and to use the available frequency spectrum in the most economical manner has led to the use of complex systems of modulation, and associated mathematical problems of corresponding complexity have arisen. For example, there is often considerable difficulty in the theoretical evaluation of the band-widths required for the transmission of certain types of signal and in the determination of the response of circuits to applied voltages. The object of Mr. C. L. Cuccia's book is to show how the Fourier series and the Fourier and Laplace transforms can be used for the solution of these and other similar problems. It is essentially a text-book on these functions and is designed particularly for the postgraduate student.

The first four chapters consist of a brief presentation of the Fourier and Laplace methods of analysis—perhaps too brief for the reader with no previous knowledge of these methods, but nevertheless a clear summary of those aspects which have direct application to communication problems. The methods are then used in a study of the influence of periodic and transient signals on various types of circuit, ranging from simple linear networks to multi-stage amplifiers. The band spectra involved in the different types of modulation are then discussed, and the same analytical methods are applied to the study of travelling waves.

The emphasis throughout is on the development of the mathematical methods, and the book is recommended to students wishing to acquire facility with these methods. Brief descriptions of practical techniques, circuits and devices are given, but are no fuller than is necessary to provide the physical background for the mathematical analysis. The problems discussed are those which occur in modern radio practice, and many of them, relating to television, transistors, cavity magnetrons and klystrons, for example, are of recent origin. The presentation is clear and errors few. Each chapter contains exercises for the student, and there are many references, nearly all to American publications.

As radio communication develops, it becomes increasingly necessary for engineers to become familiar with the more advanced mathematical methods. Mr. Cuccia's book is a valuable guide to the use of some powerful analytical tools; but it appears that even these have their limitations, and there are many problems in the solution of which an ounce of experiment is still worth a ton of mathematics. F. HORNER

THE CESTODES

The Zoology of Tapeworms

By Robert A. Wardle and James Archie McLeod. Pp. xxiv+780. (Minneapolis: University of Minnesota Press; London: Oxford University Press, 1952.) 80*s*. net.

THIS encyclopædic work on cestodes, comprised within 780 pages, including the index and a bibliography of 105 pages with nearly three thousand references, is a comprehensive study of the tapeworms known throughout the world. It attempts to summarize what is known about their classification, structure, life-histories and ways of life; it discusses theories of origin and evolution; and it provides detailed, systematic descriptions and keys for the identification of all the known families and genera and most of the known species.

Part 1, the first 169 pages, consists of five chapters. The first deals with the general features of cestodes, including information about the 'holdfast organ', a term preferred by the authors to the more conventional 'scolex', the body, skin, parenchyma, musculature, and the osmoregulatory, nervous, and male and female reproductive systems. Chapter 2 discusses the cestode life-cycle. Our knowledge of the development and life-cycle of tapeworms has accumulated more slowly than that of their general anatomy, and few tapeworm life-cycles are known completely. What information, however, is available is presented in a coherent account. Tapeworm biology is discussed in Chapter 3 from two aspects, that concerning the animal as an individual (its growth, activities, alimentation, respiration and so forth) and that concerning the animal as a member of a partnership (its relationships with other parasites and with its host, and its effects upon the host and those the host may have upon it). In Chapter 4 the various hypotheses, which are purely conjectural, as to the origin and evolution of tapeworms are given, and in Chapter 5 there is an interesting account of the history and classification of cestodes.

Part 2, the bulk of the volume, begins on p. 173 with the classification used by the authors in their book. It is of interest, to systematists at least, to note that the class Cestoda is composed of eleven orders, of which five are new, and the class Cestodaria of three orders, of which one is new. In the ensuing pages these orders are discussed, and for each there is a description, a historical review, the recognition features, and the classification of the order into families, sometimes sub-families, and genera. In the notes on each genus, mention is made of species-groups and of species, and those forms which cannot be fitted within the order or family are dealt with under the heading "Genera Inquirenda". It is difficult, within the compass of a review, to summarize the many interesting and important points raised in this part of the book, and two examples must suffice. Readers will look in vain for *Tænia saginata* and *Tænia tæniæformis*, for they are given respectively as *Tæniarhynchus saginatus* and *Hydatigera tæniæformis*. Regarding the second species, the authors mention that the establishment of genera, indistinguishable as adults, upon features of the larval stages has much to commend it, although there is much to be said against it too. Recognition of the tæniid genera *Echinococcus*, *Hydatigera*, *Multiceps* and *Tænia* on such grounds has long been the practice among American parasitologists; but this very practice opens up the question whether, in the absence of any practicable method of counting chromosomes, the specific and generic units of zoological classification shall be based upon readily recognizable characters of the adult animal, or upon features of the life-cycle and biology, a procedure which, while eminently desirable, is rarely attainable. Without taking sides in the argument, the authors have, in this matter, followed the current American practice.

The authors have undertaken an enormous task, and the result is an important and valuable contribution to zoological literature. They observe that the keys to an understanding of many obscure biological phenomena may be within these animals; but the investigator is baffled by the fragility of his material, by its brief existence when removed from its normal habitat, and by the complexity of its environmental requirements. Nevertheless, a vast literature, polylingual, scattered and fragmentary, has accumulated around them, and the authors' aim has been to present from this literature and from their own observations a coherent story of these helminths and to expose the gaps and imperfections in our knowledge of them; in this they have succeeded remarkably well. The book deserves close and attentive study, for in it are raised problems which provide a challenge and an inspiration to research. It is scarcely a text-book for the undergraduate, but a work of reference for parasitologists, zoologists and workers in various fields of biology. There will be many occasions when it will be consulted by teachers and research workers. The 419 text-illustrations—mostly line-drawings—are well chosen and uniformly good, the text is concise, up to date and lucid, and the printing and binding are all that could be desired. J. N. OLDHAM

Foundations of Analysis

The Arithmetic of Whole, Rational, Irrational and Complex Numbers; a Supplement to Text-Books on the Differential and Integral Calculus. By Edmund Landau. Translated by F. Steinhardt. Pp. xiv+134. (New York: Chelsea Publishing Co., 1951.) 3.25 dollars.

THE late Prof. E. Landau, of Berlin, was shocked to find that his daughters, who were taking a university course in chemistry and had learned calculus at school, yet did not know why *xy* was equal to *yx*. He accepted the fact that a rigorous treatment of algebra was too advanced for schools. He then examined the teaching in universities and found that they apparently often ignored the subject as being too elementary. He could not find a single text-book which dealt satisfactorily with the number system. The only thing left for him was to write such a book himself, and this he did in 1929. After a long delay, an English translation has now appeared.

Everything is based upon five axioms, due to Peano, concerning the natural numbers. The fifth of these asserts the principle of mathematical induction, which is used extensively in what follows. On this basis are established successively in five chapters the ordinary rules for the treatment of natural numbers, fractions, cuts, real numbers and complex numbers. The book is a model of elegance, precision and completeness. The author was perhaps over-optimistic in hoping that a normal student could read through it in two days. It is true that most of the proofs are very simple; but in Britain, at any rate, a normal student will be puzzled by the first words (p. 1): "We assume the following to be given: A set (i.e. totality) of objects called natural numbers, possessing the properties—called axioms—to be listed below". To appreciate this, a preliminary discussion of the nature of 'axioms', of the object of setting up axiomatic systems, and of the relation of such systems to ordinary computations and to physical science would have been helpful. On p. 43 the concise and abstract treatment of cuts may puzzle those who have not previously had a more elementary and concrete exposition of the idea. However, the book is so very good, as a whole, that it would be ungrateful to lay stress on the few points in which it might have been even better.

H. T. H. PIAGGIO

Papierchromatographie

Von Dr. Friedrich Cramer. (Monographien zu Angewandte Chemie und Chemie-Ingenieur-Technik, Nr. 64.) Zweite, neubearbeitete und erweiterte Auflage. Pp. 136. (Weinheim/Bergstr.: Verlag Chemie, GmbH, 1953.) 12.80 D. marks.

THIS revised edition of "Papierchromatographie" gives an excellent account of the literature up to the middle of 1952. It deals with apparatus, preparation and purification of solvents, and with both qualitative and quantitative analysis. All the variants of paper chromatography are included, the chromatopile, reversed-phase chromatograms, alumina and silica-gel treated papers, and papers containing free carboxyl groups. The analysis of amino-acids, sugars, purines, nucleotides, nucleosides and nucleic acids and of inorganic ions are dealt with in some detail. Alcohols, phosphoric esters, phenols, organic acids and bases, vitamins, antibiotics, porphyrins, sterols and synthetic dyestuffs are not considered at such length.

The arrangement of the book is pleasing and the diagrams and colour prints of chromatograms are clear and well presented. The comprehensive lists of R_F values provided are useful, as is the transparent scale for the direct measurement of R_F values on the chromatogram. The transparent map of amino-acid spots from a two-dimensional chromatogram is of restricted usefulness, as it does not cover all the amino-acids normally encountered. Though it is perhaps a pity that the detection and elimination of faults in chromatograms are not dealt with at sufficient length (a common fault of books on this subject), the book can be recommended to all those using the technique of paper chromatography.

Through Movement to Life

The Economic Employment of the Disabled. By John Arthur. Pp. 93+6 plates. (London: Chapman and Hall, Ltd., 1952.) 7*s.* 6*d.* net.

A PROBLEM which causes great concern to employers and all who have social consciences —these two groups are not necessarily exclusive—is the employment of disabled people. In the United Kingdom there are tens of thousands of such unfortunates, including those who have lost a limb, epileptics, spastics, people suffering from rheumatism and arthritis, the deaf and the blind. Most of them are anxious to work, if only to maintain self-respect, and a nation needing labour should be able to make use of their services. In this little book, Mr. John Arthur describes an enterprise which he organized to show how the disabled could work for their own and the community's interests. The enterprise was a furniture factory which was 'sheltered' in the sense that the disabled employees did not have to compete with able-bodied workers and that the factory was not run primarily for profit. Although the venture lasted no more than three years, during that time Mr. Arthur, as managing director, learned a great deal about the means of helping the disabled. This he has set down in a book which is not always free from the ills attending enthusiasm, but which will be of value to all engaged on similar ventures.

T. H. HAWKINS

The Genetics of Garden Plants

By M. B. Crane and W. J. C. Lawrence. Fourth edition. Pp. xvii+301. (London: Macmillan and Co., Ltd., 1952.) 20*s.* net.

THE fourth edition of this popular book, first published in 1934, is said to be amended and revised in accordance with recent research. The brief account of heterosis has been amplified and enlarged in a new Chapter 8 of ten pages, though the exposition of this still mysterious phenomenon follows a stereotyped pattern common to a large number of text-books and fails to mention the now widely current theory that heterosis is mainly due to the advantage of heterozygous phases of growth genes over the homozygous phases.

One gets the impression that the authors are now largely resting on their oars. The last edition was published in 1947, and in spite of the great progress which has been made during the past five years it is disappointing to find reference to eight publications only since that year. Some of these are of minor value, and others lack relevancy to the present state of our knowledge.

The book will no doubt continue to be largely read by horticulturists, and in spite of some obvious omissions it is both useful and valuable to have so much otherwise inaccessible material brought together between two covers.

S. C. HARLAND

ELECTRICAL INSULATING MATERIALS

A SYMPOSIUM on the subject of electrical insulation, held at the Institution of Electrical Engineers during March 16–18, provided a very interesting picture of the vast amount of research work that has been, and is being, done on this subject throughout Great Britain in all the laboratories associated in one way or another with the electrical industry. It is generally realized in the industry that the limitations of existing insulating materials constitute a formidable barrier to progress in many of its branches: voltage-gradients and working temperatures must always be kept well below the limits at which the risk of breakdown becomes appreciable, and great elaboration of design is sometimes necessary to ensure that the essential characteristics of the dielectrics employed are not adversely affected by temperature and humidity. Engineers are therefore continually investigating the processes involved in the normal operation of dielectrics and those in which breakdown occurs; they are no less concerned with the possibilities of new materials and methods of estimating their efficacy and durability under service conditions. Some thirty-two original investigations covering all these aspects of the problem came under review during the five sessions of the symposium. Consideration of the details is not possible in a short article; but a few of the points of more general scientific interest will give some idea of the present position in this field of work.

Permittivity and Power Loss

The first topic considered was the nature of the processes involved in the normal operation of insulating materials of the types used in industry: that is to say, the processes characterized by permittivity (or dielectric constant) and loss angle, the phase difference between the electric displacement within the material and the applied electric field that produces it. The importance of these quantities to the electrical engineer lies in the part that they play in determining the voltage distribution (within an insulating system), the corresponding current distribution, the precise relation between these two distributions (that is to say, the impedance, phase angle and power factor of the system) and also the temperature distribution in the state of thermal equilibrium attained under normal working conditions. The voltage-gradients and impedances (or the corresponding admittances and capacitances) are, of course, almost completely determined by permittivity alone, but the loss angle, although negligibly small for the best dielectrics, is the dominant factor in determining the power dissipated within the material and is therefore of great importance in connexion with thermal equilibrium. The product of permittivity and loss angle, or strictly speaking its tangent, is proportional to the energy dissipated within the specified material during each cycle of the applied voltage. Even the smallest loss angles therefore tend to become significant when the number of cycles per second is of the order of, say, 10^{10}, which is about the upper limit of the electrical range of frequencies—the centimetre and millimetre waves. In this region, electrical and optical techniques merge into one another, and it was appropriate therefore that, in one paper, Dr. W. Culshaw (Telecommunications Research Establishment) described a spectrometer method by which permittivity and loss angle can be measured for flat sheet material traversed by millimetre waves. The method has been shown to be practicable but has not yet yielded data beyond the reach of the established electrical methods which were employed by the other contributors—bridge methods for the lowest frequencies, circuit-resonance methods for the main radio range, and cavity resonators for centimetre waves.

The data for most of the materials of interest to engineers are of great complexity, and we are still far from a full understanding of the processes involved. The main characteristics of the simplest ones are, of course, well known. Part of the electric displacement is always such as can be visualized as a displacement of the electrons with respect to the atomic nuclei, a process having a natural frequency in the optical range and capable of accounting for the optical index of refraction of the material. If no additional process occurred at electrical frequencies, the dielectric constant would be equal to the square of the optical refractive index and the loss angle would be zero, since this fast displacement follows the slow electrical cycles with no appreciable lag. This condition was shown by Dr. L. Hartshorn, J. V. L. Parry and E. Rushton (National Physical Laboratory) to hold remarkably closely for the pure hydrocarbon plastics and the fluorocarbon polytetrafluorethylene. Any loss angle observed in such materials in practice can only arise from accidental impurities. The permittivity of such materials is independent of frequency but diminishes with rise of temperature by an amount corresponding with the linear expansion of the material.

Most other materials show a permittivity considerably greater than the square of the optical refractive index and therefore call for a consideration of two other displacement processes. The first is the displacement of different atomic nuclei with respect to one another, a process which may be expected to have a natural frequency in the infra-red region—that is to say, still far enough above the electrical frequencies to give rise to no appreciable loss angle in electrical work. The second additional displacement is that arising from changes in the orientation of molecules or groups of atoms having a permanent dipole moment, changes which are characterized by a time-constant or time of relaxation rather than a frequency of vibration. The extent to which this displacement occurs, during each half-cycle of the applied field, depends on the relative values of the time constant and the duration of the half-cycle; but at frequencies for which the two are of the same order, the permittivity increases rapidly as the frequency falls and so gives the dipole orientation appreciably more time to develop, while at the same time the loss angle rises to a maximum value, which again diminishes to zero when the cycle becomes so slow that the dipole orientation follows the field without appreciable lag. The relaxation time is strongly dependent on temperature, and therefore both permittivity and loss angle are liable to vary greatly with temperature as well as frequency, and there is a necessary connexion between the variation of the two quantities. A paper by A. C. Lynch (Post Office Research Station, Dollis Hill) discussed this question in its bearing on the temperature coefficient of mica capacitors, emphasizing that the temperature coefficient for radio uses is liable to be quite different from that for low frequencies. The time constants of the electric displacements within the material may not in this instance arise from dipolar molecules; they may arise from differences in the distribution of resistivity and permittivity in a composite dielectric in accordance with classical theory as developed by Maxwell, but since such time constants are also temperature-dependent the same considerations apply. Dr. A. Fairweather and E. J. Frost, also of Dollis Hill, applied this simple theory to semi-conducting aggregates such as the ferrites, used primarily for their magnetic properties, though their dielectric properties are not without some influence on their performance in communication circuits. The dielectric properties, though complicated, were shown to be adequately accounted for by a network of capacitors and resistors each corresponding to some simple recognizable feature of the composite material.

Hartshorn, Parry and Rushton were particularly concerned with the dipolar process in the silicones and in representative plastics. All the long-chain silicones show a peak in the curve for loss angle at frequencies between 10^{10} and 10^{11} c./s., and it is inferred that the corresponding relaxation time, which is independent of chain-length, is characteristic of the Si—O linkage in flexible linear chains. The permittivity and loss angle of the water-absorbent plastics have been shown to be very largely dominated by the absorbed water; but it is striking that the values for the completely dried materials, though smaller, are of the same general character as those for which the water is responsible. In other words, the absorbed water molecules behave in the electric field almost exactly like the polar groups in the structure of the pure resin, and not like free water. The main features of the observed properties are found to correspond well with a model given by Fröhlich as an extension of Debye's theory.

A. Turney (Imperial College of Science and Technology, London) reported an attempt to find evidence for a resonance process suggested by Fröhlich as also associated with the dipoles, by examining benzene derivatives having a structure considered to be most favourable for such a process; but the evidence was negative, the above-mentioned model accounting for all the observations.

Liquids

A session devoted to liquids brought out the fact that in British electrical practice the one liquid that is of supreme importance is mineral oil, transformer oil and the like. Broadly speaking, it can be regarded as a paraffin oil, initially pure but subject to contamination in use. Its primary function is to exclude moisture and air from solid insulation, usually cellulose in the form of paper or pressboard, which supplies the required mechanical properties, but only behaves as a good dielectric so long as moisture or damp air are denied access to it. The papers and discussion clearly reflected the great importance in heavy electrical engineering of the paper and oil combination, and the effect on it of moisture and other contaminants. J. Dunkley and Dr. R. W. Sillars (Metropolitan Vickers Electrical Co., Ltd.) showed that, when the oil is very highly refined, far beyond the ordinary commercial limit, it shows no measurable loss angle even when damp air is blown through it. If, however, it contains a trace of an ester, which itself produces no loss angle at low frequencies, it develops a comparatively large loss angle when allowed access to damp air. The power loss is shown to be associated with ionic conduction; the conductivity varies with the applied field because of the effect of the field on the balance between the dissociation and recombination of ions, and with the frequency because the relaxation time of this process is comparable with the periodic time of the applied voltage.

In practice the oil commonly rises in temperature to a value near 100° C., one of its functions being to promote cooling by convection, and the high temperature with some access to air introduces further complications of great practical importance. K. H. Stark reported an investigation carried out by the Electrical Research Association into the behaviour of ordinary oil under these conditions. The oil, when at 20° C. or thereabouts, normally has a power factor, probably due to traces of some ionized constituent, that is very small, but accurately measurable provided the greatest possible care is taken to ensure that the capacitor in which the oil is tested is chemically clean. R. G. Martin and E. A. Patterson (Shell Petroleum Co., Ltd.) showed that the capacitor must be dismantled and the parts boiled in trichlorethylene before each test in order to ensure that the values are truly representative of the oil. Even when this is done, no unique value is obtainable for a sample of oil at 100° C. Oxidation of the oil occurs, and Mr. Stark showed that its effect on the loss angle is a rapid diminution, which is followed by an increase. The action is accelerated by the presence of metal in the oil, probably by catalytic action at the metal surface. The quality of an oil cannot therefore be assessed by any single measurement at the working temperature.

In practice the slow continued oxidation leads to the development of acidity and conductivity in the oil, the formation of sludge, an increase in the power factor of the paper–oil mixture, and a consequent reduction of the voltage at which thermal instability would occur. Rusting of metallic iron in the system also occurs, and some of the iron compounds formed may go into solution; others may merely add to the sludge, which may ultimately become harmful by impeding the convection cooling action, but does not necessarily affect the dielectric properties to a serious extent. D. G. Childs and A. W. Stannet (British Electricity Authority) reported some interesting observations on oils that had actually been in service in various localities for periods ranging from one to twenty-four years. Simple tests of acidity and conductivity were used as an indication of condition, but conductivity did not show good correlation with acidity alone. Variations in iron content had a marked effect, and must be taken into consideration if acidity is used as a criterion of insulating quality. Their survey indicated an expectation of life of thirty-five years for the oils in general use.

Breakdown

The session devoted to a consideration of electric strength and breakdown mechanisms attracted a very large audience, for the avoidance of breakdown is a vital consideration in every electrical design. The papers, particularly one by H. F. Church and C. G. Garton, of the Electrical Research Association, emphasized the fact that breakdown such as is liable to occur in practice is a process far more complex than those represented by permittivity and power factor or indeed than any other occurring in electrical equipment. To the casual observer the breakdown is an instantaneous catastrophic collapse of the structure of the material, and the idea that any given material will withstand indefinitely voltage gradients up to a certain critical value, characteristic of its structure and known as its electric strength, arose naturally from the first tentative studies of the phenomenon. It is now abundantly clear that, although it is possible to determine, by voltage applied under highly special conditions, limiting voltage-gradients of this kind which are indeed characteristic of the atomic structure of the materials, yet this intrinsic electric strength is of comparatively minor importance in the much larger question of breakdown under ordinary working conditions. The intrinsic breakdown strengths of all ordinary solid and liquid insulating materials are in the region of a few MV./cm., and they vary comparatively little with temperature and from one material to another, whereas in ordinary practice breakdown commonly occurs at an apparent voltage-gradient which is no more than one-tenth of this value; moreover, the observed value has no clear relation to the structure of the material and is greatly influenced by many other variables such as temperature, duration of application of the voltage, etc. The central problem in research on electrical insulation to-day is not so much to increase, or even to explain, intrinsic electric strengths as to raise the applied voltage-gradient at which breakdown occurs under ordinary practical conditions. C. G. Garton made the point that even halving the gap between the intrinsic electric strength and the electric strength as measured under ordinary working conditions would make possible revolutionary improvements in design.

Intrinsic electric strength was, however, not neglected. A paper by J. H. Calderwood, R. Cooper and A. A. Wallace (University of Liverpool) showed that mechanical strain may increase the value for a crystal, so that the highest value obtained for a given sample is not necessarily the true one. Another paper, by Dr. T. J. Lewis (Queen Mary College, London), described a satisfactory technique for obtaining values truly characteristic of pure organic liquids.

Breakdown at the intrinsic electric strength is an electronic process which has been reasonably well explained by the work of Fröhlich and others; breakdown under ordinary working conditions is usually a complex chain of processes, of much longer duration than the intrinsic breakdown, and perhaps including an intrinsic breakdown as part of the chain but sometimes including processes that might be described as chemical rather than electrical. Moreover, it is not a question of a well-defined chain characteristic of a material, but of a number of possible chains, the choice depending on factors the presence of which may not be suspected—for example, the presence of sub-microscopic voids or gaseous inclusions, or ions having particular chemical properties. In this state of extreme complexity, progress is perhaps best made by isolating and studying the component processes separately, and this is what many workers are doing.

For example, papers by Dr. E. Friedlander and J. R. Reed (General Electric Co., Ltd.), by W. L. Harries (University of Oxford) and by J. H. Mason (Electrical Research Association) were all concerned with breakdown processes which include as the dominant feature discharges in a gas enclosed within solid insulating walls. Nearly all industrial materials contain such gaseous inclusions, which may or may not be visible: the voltage-gradient within them tends to be relatively high, and the electric strength of the gas is relatively low, so that discharges occur at moderate overall voltage gradients. Such discharges do not necessarily lead to breakdown of the insulation as a whole; indeed, a speaker claimed that bushings in which discharges had been detected under working voltages had been known to function satisfactorily for twenty years. However, the bombardment of the walls of the enclosure by the ions carrying the discharge may produce actual erosion of the material and a local concentration of field, which may develop progressively until complete breakdown follows. Local concentrations of field within microscopic or smaller regions of the material are probably the key to the whole problem, for, if the local stress rises to the intrinsic electric strength, local breakdown necessarily occurs and there is a probability of it developing progressively or of stimulating some chemical or thermal change which develops progressively under alternating voltage. A paper by H. G. Riddlestone (Electrical Research Association) presented evidence supporting the view that the breakdown of both polythene and polystyrene under A.C. conditions involves the development of intensely local rises of temperature, though the mechanism by which it occurs in such low-loss materials is by no means obvious.

Breakdown by thermal instability is much less surprising in the oil–pressboard combination mentioned in connexion with liquids, for the power factor is greater and its increase with rise of temperature directly measurable. R. T. Rushall (British Thomson-Houston Co., Ltd.) showed that the breakdown voltage, as judged by a straightforward one-minute test, is closely associated with the measured loss factor, irrespective of varying temperature and moisture content. This clearly indicates thermal instability as setting the limit to the safe working voltage-gradient, and moreover provides a method of estimating the risk of breakdown by a measurement of permittivity and power factor at a perfectly safe voltage.

Breakdown by short voltage impulses is usually closely related to the intrinsic electric strength, and Dr. B. Salvage (W. T. Henley's Telegraph Works Co., Ltd.) showed that the observed values for cables are very much what would be expected from the known values of intrinsic electric strength and permittivity of the constituent materials.

New Materials

Comparative studies of new and old materials for specific purposes naturally attracted much attention at the symposium: for example, the various types of impregnating varnish, the newer laminated materials, materials that have been tried in rotating machines and the special ceramics available for radio uses.

In matters of fine detail and on the comparatively small scale, chemical advances have played a prominent part. Consider, for example, the impregnating varnishes; coils wound with cotton-covered wire are impregnated with varnish which is then hardened, this being an economical process for producing a structure that is mechanically rigid and well insulated throughout, provided the varnish has just the right penetrating, hardening and insulating qualities. R. Newbound and R. T. Rushall (British Thomson-Houston Co., Ltd.) and H. R. Heap (Crompton Parkinson, Ltd.) reported on this matter. It is perhaps not surprising to find that thermo-setting varnishes incorporating phenolic resins tend to provide a better mechanical job than the older oil-oxidizing varnishes, but it would have been difficult to foresee that the use of phenolic varnish would lead to less oxidation and sludge formation when the coils are operated in oil, either by more effective covering of the copper surface, which acts as a catalyst, or by some direct inhibiting action. The difficulties of devising tests for the required combination of qualities are obvious.

On the larger scale the impression left is that chemical advances have not influenced practice so much as might have been expected. Traditional materials like mica, shellac, paper and mineral oil still seem to dominate the whole picture. It is true that polyethylene, polystyrene and the new ceramics have made possible important advances in the radio and radar fields, that glass fabrics, nylon, terylene and the silicones introduce the possibility of improvements in particular directions at a cost which may not be prohibitive, and these and many similar matters received due consideration; but no contributor was found to suggest that any revolution in practice on the large scale is in sight.

Nevertheless, the symposium as a whole gave an encouraging picture of activity and progress on a very wide front; the many widely scattered workers thus brought together for the first time appreciated its stimulating effect, and the industry cannot fail to benefit in due course as the ideas and knowledge assembled become more widely disseminated throughout the main body of its members.

L. HARTSHORN

ORGANIC MANURES AND FERTILIZERS

IN the Section of Comparative Medicine of the Royal Society of Medicine a discussion was held on May 20 on "Organic Manures and Fertilizers and the Production and Composition of Food for Man and Animals". The president of the Section, Prof. C. L. Oakley, was in the chair and introduced the speakers.

Sir William Ogg (Rothamsted), who opened the discussion, outlined the present position and dealt with the soil aspects of the question. In order to maintain or increase fertility it has, from very early times, been the practice of farmers in most parts of the world to return to the soil, crop residues, animal manure and domestic waste and to rest the land for periods under grass. If production is not too intensive, this system is usually quite successful provided there is not a deficiency of some essential mineral nutrient. With increasing population and its concentration in towns, new problems have arisen. Through modern systems of sanitation, much of the manurial residue which used to find its way back to the land is now carried as sewage to the sea. The introduction of fertilizers just over a century ago enabled farmers to make good these losses and also to increase production. They have not superseded farmyard manure, which, in addition to its manurial value, has important physical effects on the soil; but they are a source of additional plant food and without them the present population of the world could not be fed. It has been estimated that, in terms of readily available nutrients, the total amount of farmyard manure made annually in Great Britain provides only about a third of the nitrogen, a quarter of the phosphate and half the potash applied in the form of fertilizers. Fertilizer consumption has practically trebled in Britain and the United States in the past fifteen years and this has been a major factor in increasing food production.

Attempts have been made to create a controversy over the respective merits of organic manures and fertilizers. The conflict of opinion is, in fact, between those who advocate a proper use of both and a very small minority who oppose the use of fertilizers. It is sometimes alleged that fertilizers poison the soil and are injurious to the health of plants, animals and human beings. There is no sound evidence to support these views, provided that fertilizers are properly used. They do no harm to the earthworms or to the bacteria and other micro-organisms; nor do they bring about soil erosion. There is no evidence that they render plants more liable to suffer from insect, fungus or virus attacks. Organic manures and fertilizers are complementary, and in good farming practice both are employed.

Dr. G. C. Ainsworth (University College, Exeter), as a botanist and microbiologist, directed attention to the complexity of the total situation which determines health and disease in plants and of which the soil–plant interaction is only a part. Green plants are not dependent on the soil for their carbon, but they are for their other nutrients. Under natural conditions, plants die and decay *in situ* and so repay their debt to the soil together with interest in the form of organic matter. On cultivated land, man periodically removes a crop, and this inevitably leads to a depletion of the soil which must be made good. In primitive societies the exhausted soil is abandoned —an impossible procedure in more advanced and densely populated countries, where a balanced use of chemical fertilizers would appear to be the rational and most convenient way of maintaining the nitrogen, phosphorus and potassium, that trinity of elements basic for plant growth. Chemicals, too, are an appropriate source of the small quantities of boron, copper or other 'trace elements' which may render an unsatisfactory soil fertile.

An agricultural soil has not the simplicity of a controlled and mechanically irrigated sand culture. The organic matter it contains has a vital role in conserving moisture and in providing a substrate for the growth of micro-organisms which, in their turn, affect the physical condition of the soil by determining crumb structure and in making available materials which can be utilized by higher plants. At the same time, the microflora competes with the higher plants for nutrients, and certain fungi may cause disease, while another class, the mycorrhizal fungi, set up a symbiotic relationship with higher plants. The use of farmyard manure is the age-old solution to the problem of maintaining both the inorganic and organic constituents of the soil and the microbial population, but the advent of the internal combustion engine has rendered this solution inadequate and new sources of organic manures are having to be explored. Sometimes it is necessary to introduce the requisite symbiont for a particular plant when the plant is grown in a new situation. Finally, the summation of the soil–plant interaction, as manifest by the response of the plant to the weather and the pathogen, was touched on and the recent work on systemic fungicides and insecticides recalled, for it is possible that plants absorb such substances from the soil.

Dr. David P. Cuthbertson (Rowett Research Institute) dealt with the relationship of manures to the health of man and animals. He pointed out that no amount of composting can return to a farm the products which move out of it in the form of crops and livestock, and that the use of natural organic manures alone cannot supply the trace elements which are deficient over considerable areas of the world. Australian agriculture would largely collapse without fertilizers.

The advocates of organic farming state that the full benefits of composting, the four-year ley and grazing as fertilizing agents are not achieved by orthodox farming, since the manure from livestock fed on concentrates will be deficient in certain essential minerals. There is no evidence to support this generalization, always provided that there is intelligent balancing of fertilizers and farmyard manure, and that the soil is not intrinsically deficient in some minerals.

Regarding the effect on protein and the free amino-acids, there is no evidence that the application of fertilizers has any adverse effect on total amino-acid content. Man consumes a variety of proteins of both vegetable and animal origin and the essential amino-acid requirements are generally met. This may also be said for non-ruminant farm stock; in the case of the bird, special care has to be exercised so that all critical amino-acid requirements are covered. The ruminant is well protected against amino-acid deficiency owing to the microbial activity in the fore-stomach.

The genetic stability of plants is generally of greater significance than climate, soil or fertilizer treatments in respect of vitamin content.

The increased use of fertilizers has not affected adversely the general decline in infant mortality or the increase in the expectation of life of man. The best health conditions which can be observed are compatible with the general consumption of foods grown on chemically manured soil. The health statistics of the Netherlands are as good as those of Great Britain, although the fertilizer consumption of the former is five times the latter per unit of agricultural land. Again, the United Kingdom health statistics are as good as those of Eire, while the corresponding ratio of fertilizer consumption is about 3 to 1.

The belief that the improvement in grassland culture has led to an increase in the so-called metabolic diseases of cattle has not been proved.

Until proof has been obtained that the heavy application of fertilizers may give rise to disease in man or beast, the use of fertilizers as practised in orthodox farming is to be recommended as a means of increasing food production in Great Britain.

Sir James Scott Watson (Ministry of Agriculture) dealt with the maintenance of soil fertility in the future. Our present knowledge is in part the result of farming experience built up over some eight thousand years, and in part the product of scientific investigation during recent times; and Sir James discussed some of the problems of reconciling science and tradition. The list of essential plant nutrients is now probably complete; the chemist can produce a solution of pure salts, in distilled water, that will support normal plant growth, and we have no evidence that the plant products when fed to experimental animals are in any way deficient in nutrient properties. Plant growth, however, depends not only on nutrients but also on a reasonably constant supply of water, and root activity demands a supply of oxygen and is inhibited by a relatively low concentration of carbon dioxide. These requirements imply the maintenance of crumb structure, and loss of this structure is one of the major causes of erosion by wind and water.

The maintenance of good structure depends on several factors. One of these is tillage at the right time when the soil has an appropriate moisture content and when frost and thaw can play their part. Another is the nature of the soil minerals; sandy soils can be improved by applying clay and marl or vice versa. Yet another is the provision of a mild binding agent, and the natural one consists of the colloidal decomposition products of organic matter. The organic matter may be partially decayed as in farmyard manure and composts, or it may be undecayed; and in the latter case the rate of decomposition depends in the main on the ratio of carbon to nitrogen compounds. More research is required on the balance between the grass and clover components of pasture and on management. The practice of growing crops specially for 'green manuring' also deserves further study, and probably the most promising are quick-growing grasses with very heavy seedings and high applications of fertilizers. Sewage sludge, preferably composted with straw, is a useful source of organic matter but is costly to transport and handle. Certain synthetic plastics have recently been shown to be effective in stabilizing an existing crumb structure, but the immediate obstacle to their general use is their high cost.

GEOLOGICAL SURVEY BORING IN GREAT BRITAIN

At a meeting of the Geological Society on July 1, Dr. W. J. Pugh, director of the Geological Survey of Great Britain, gave a brief account of the investigations by boring carried out within the past year by the Geological Survey.

Proposals for a programme of Survey boring were made in 1945 by a Committee of the Advisory Council of the Department of Scientific and Industrial Research; and since then several deep boreholes have been drilled as the work of the field staff and the availability of funds have permitted.

Summary accounts of the results obtained from four of these boreholes, one in Needwood Forest (Staffs), one at Whittington Heath (Staffs)[1], one at Stowell Park (Glos) and one at Rashiehill (Stirling), have been published or are in the press. From four other holes, one of them not yet completed, important information has been obtained; and Dr. Pugh gave an outline of the results so far to hand and referred to the deductions to be drawn from them.

Ashton Park. In the Bristol and Somerset Coalfield the strata between the Carboniferous Limestone Series and the Coal Measures are masked by Triassic deposits at the surface and had not been adequately seen either underground or during boring operations. In order satisfactorily to elucidate the structure of the field, the geological survey of which has been recently completed on the scale of 6 inches to the mile, it was necessary to prove the thickness and sequence of these strata; and for this purpose a borehole at Ashton Park, Bristol, was started in July 1952 by Messrs. John Thom, Ltd.

The bore reached a depth of 2,195 ft. Triassic rocks, consisting of sandy red marls, were found to a depth of 130 ft. They rest on Coal Measures, 578 ft. thick, in which three coals were encountered, namely, the Ashton Top, the Ashton Great and the Ashton Little seams. Apart from a 20-ft. band of non-marine lamellibranchs above the Ashton Little Seam, the Coal Measures to this depth have proved singularly barren of plant and animal remains. Below the Ashton Little Seam, however, marine strata with *Lingula* were found between 572 ft. 7 in. and 726 ft. 5 in. The Ashton Vale Marine Bed lies between 687 ft. 5 in. and the bottom of the Coal Measures at 708 ft. 2 in. It contains many goniatites, including the characteristic *Gastrioceras subcrenatum*. A Quartzitic Sandstone group of strata extends from the base of the Coal Measures to a depth of 1,315 ft. and consists mainly of hard quartzose sandstones. There are interbedded shales near the top and chert beds, resembling those of Culm type, in the bottom 80 ft. This group probably corresponds roughly to the Millstone Grit of northern England. Below 1,235 ft. sandstones give place downwards into limestones by alternation. Both are considered to belong to the Carboniferous Limestone Series and to represent the uppermost part of the sequence exposed in the Avon Gorge. Below 2,000 ft. the bore passed through the limestones forming the passage between the D_1 and S_2 subzones (in terms of Vaughan's zonal nomenclature).

Upton, Burford. In 1875 a borehole, possibly in search of iron ore, was put down near Burford Signet Farm, Burford, Oxon. It was stated by De Rance to have proved Coal Measures beneath Trias, but published records are inconclusive. The detailed record of a later borehole at Batsford, Glos, about sixteen miles to the north, showed that barren Upper Coal Measures beneath Trias were 524 ft. thick and rested on Silurian rocks. These facts, and the great thickness of Triassic rocks found in the Stowell Park Borehole, some ten miles west of Burford, were the main factors leading to the decision to bore again near Burford.

Drilling was commenced by Messrs. Craelius Co., Ltd., in August 1952. Starting at the base of the Inferior Oolite, the bore proved the Upper and Middle Lias to be thin, whereas the Lower Lias (460 ft.) and the Trias (525 ft.) were of such thickness as had been anticipated.

Upper Coal Measures were entered at 1,105 ft. and were proved to a thickness of 2,664 ft. These non-productive measures are alternating red and grey in colour and contain thin coals. In character they are comparable with parts of the higher Coal Measures sequence in South Staffordshire and with some in the Bristol district. Thin limestones occurred at two levels, the lower containing *Spirorbis*; gastropods were found at both horizons. No plants of age other than Staffordian have yet been detected.

Canvey Island. The possible existence of coal-bearing strata under south Essex has long been discussed, and a view that a basin of such measures lay under the Thames Estuary was advanced following the findings of a gravity survey by the D'Arcy Exploration Co., Ltd.[2], which showed a pronounced gravity 'low' extending beneath the estuary between Canvey Island and the Isle of Grain. Such evidence as was available from other deep bores in neighbouring areas was not wholly favourable to this view, but the gravity anomaly was considered to warrant investigation by boring. Drilling was commenced in January 1953 by the Bremner Well-Drilling Co., Ltd. Coring was started in the Upper Greensand at a depth of 1,200 ft. The underlying Gault extended to 1,320 ft. 6 in. and rested with angular disconformity upon a sandstone-mudstone sequence continuing to the bottom of the hole at 1,750 ft. Fragmentary plant remains and ostracods indicate an age not younger than Middle Devonian and not older than Downtonian.

Cambridge. Seismic reflexion work[3] had indicated the probability that the surface of the Palæozoic strata under the Mesozoic rocks in the Cambridge area was about 360 ft. below O.D., and Prof. W. B. R. King initiated a scheme to investigate this point by boring. The Royal Society and various industrial firms made grants towards the cost of the borehole and ultimately the project was undertaken jointly with the Geological Survey. The site of the bore is near that chosen for the future extension of the geophysical laboratories at Cambridge, and the hole is being kept permanently open to provide opportunity for instruction and research in geophysics in the University.

Boring was commenced in October 1952 by Messrs. George Stow and Co., Ltd. The Palæozoic floor was struck at a depth closely in accordance with the geophysical estimates, but the Carboniferous Limestone of which it consists was not expected. As the Jurassic strata gave promise of valuable information they were cored throughout. The formations proved include Gault to 138 ft. depth, Lower Greensand (31 ft. 6 in.), Corallian Beds (9 ft. 6 in.), Oxford Clay (159 ft. 2 in.), Kellaways Beds (10 ft. 6 in.), ? Upper Cornbrash (7 ft. 10 in.), 'Great Oolite' (4 ft. 3 in.), Upper Estuarine Beds (31 ft. 3 in.) and Lower Lias (41 ft. 3 in.) to 434 ft. depth. This last rests on Carboniferous Limestone which at 590 ft. depth has not yet been bottomed. The limestone, of which 157 ft. has been cored, is highly dolomitic and appears to belong to the lower half of the Carboniferous Limestone Series.

OBITUARIES

Prof. Samuel Smiles, O.B.E., F.R.S.

Dr. Samuel Smiles, emeritus professor of chemistry in the University of London, died at Tunbridge Wells on May 6 after a short illness. He was born in Belfast on July 17, 1877, the son of Samuel Smiles, of Beckenham, and grandson of the well-known writer of the same name. Educated at Marlborough, he entered University College, London, in 1894, graduated B.Sc. in 1897, and D.Sc. in 1901. His thesis for his doctorate included his early contribution to the stereochemistry of sulphur, published in 1900.

During 1900–2 Prof. Smiles was on the Continent, working with Moissan in Paris and Knorr in Jena. At the commencement of the 1902–3 session he was appointed an assistant in the Department of Chemistry in University College, London, and became assistant professor in 1907, a post he held until 1919, when he was appointed to the chair of organic chemistry at Armstrong (now King's) College, Newcastle upon Tyne. At Easter 1920, he succeeded the late Prof. Crossley as Daniell professor of chemistry, King's College, London, where he remained until his retirement in 1938.

During the First World War, he was engaged upon problems connected with tracer ammunition, and for these services received the O.B.E. in 1918. In that year also he was elected a Fellow of the Royal Society. He was a Fellow of both University College and King's College, London, and an honorary D.Sc. of Queen's University, Belfast.

Prof. Smiles rendered considerable service to the chartered chemical bodies. A Fellow of the Chemical Society from 1898, he served as secretary during 1912–20, and was a vice-president during 1920–23. He became a Fellow of the Royal Institute of Chemistry in 1916, was examiner in general chemistry for the associateship during 1920–24, and a member of Council during 1931–35 and 1936–39.

In 1920 he married Minnie, youngest daughter of the late G. N. Patterson, of Newcastle, who survives him. During most of the war and post-war period, Prof. and Mrs. Smiles lived at Inverness, but had quite recently returned to Tunbridge Wells, where they had resided during his tenure of the King's College professorship.

Almost all Prof. Smiles's published papers, numbering more than a hundred, are concerned with organic compounds of sulphur (or selenium). The only exceptions are those with Moissan on silicon and silicon hydrides; that with Knorr on β-methylmorphimethine; and his last three papers. His studies touched on many different types of sulphur compounds, including sulphonium bases, sulphoxides, sulphinic and sulphenic acid derivatives and cyclic compounds. Typical investigations were those on disulphoxides, which were shown to be thiolsulphonic esters; and on the two isomeric sulphides of β-naphthol. As early as 1911, he had been interested in the problem presented by the β-naphthol sulphides; with his collaborators he elucidated it in a long series of papers, and showed the interconversion of the two compounds to be a special example of what came to be called 'the Smiles' rearrangement'. His last three papers were concerned with other examples (not sulphur compounds), including aryl salicylates and *o*-carbamyl derivatives of diphenyl ether. Appropriately, all this work was adequately summarized, just after Prof. Smiles's retirement, in the *Annual Report on the Progress of Chemistry* (36, 197; 1939).

Except the work published with Moissan in the *Comptes rendus* of the Paris Academy of Sciences and a few papers in the *Berichte*, all Prof. Smiles's papers appeared in the *Journal of the Chemical Society*, its *Proceedings* and *Transactions*. His only published book was "The Relations between Chemical Constitution and some Physical Properties", published in 1910. It was never reprinted and copies are not easy to come by. Although progress both of accumulation of data and of underlying theory has left the book behind, it still has interest as an introduction to its subject.

Valuable as his research work was, it is even more as a teacher that Prof. Smiles will be remembered. In the period 1917–19 at University College, he lectured on systematic inorganic chemistry as well as organic, and at King's College he always maintained the excellent practice of lecturing on inorganic chemistry to the first-year students. He was accustomed to say himself that one of the most difficult tasks of those in academic life was to maintain a proper balance between research and the teaching and training of students. In his later years, he tended to shift the balance towards the teaching side, and indeed to regard research as a part of student training. He came to have a fine reputation as a teacher, and to have been a student under Smiles was a recommendation in itself.

His interest in his students did not stop short with their academic life; he was a kind and wise adviser on their choice of employment, and took a deep and practical interest in their subsequent careers. The affection and esteem in which he was held by his old students and colleagues were evident on his retirement, and are simply expressed by the inscription in the watch which they presented to him in the autumn of 1938: "Samuel Smiles—Teacher and Friend".

Reginald Child

Prof. A. Mittasch

On June 4 last, Prof. Alwin Mittasch died in Heidelberg in his eighty-third year. He started as a chemist, studied the then mysterious phenomenon of catalysis under Ostwald and was later commissioned by Carl Bosch in Ludwigshafen to find a method of putting into commercial production Fritz Haber's experiments on the catalytic formation of ammonia from nitrogen and hydrogen. In this he was fully successful. Later he broadened his studies and thoughts about catalysis so considerably that in 1948 he published a book under the title "Von der Chemie zur Philosophie". The philosophical aspect of catalysis is release (*Auslösung*)—a relation between cause and effect which does not obey energetic laws, such as, for example, the action of the will. These trains of thought brought Mittasch into contact with Robert Mayer, and he published a great number of essays dealing with Mayer's writings. In the last year of his life Mittasch published two books of considerable importance—"Friedrich Nietzsche als Naturphilosoph" and, quite recently, "Erlösung und Vollendung". Mittasch enjoyed the rather exceptional honour of being made member of the Heidelberg Academy of Science without being a university professor, but, on the occasion of his eightieth birthday, the title professor was awarded to him. Up to his last illness, which led to his death within a few weeks, the old scholar was in the full possession of his mental powers and incessantly busy writing articles and answering, mostly by return mail, the letters of a wide circle of friends which his enthusiastic temperament and his kind nature attracted to him.

Miss Henrietta Jex-Blake

Miss Henrietta Jex-Blake, who died on May 21 at the age of ninety, was principal of Lady Margaret Hall, Oxford, during 1909–21. Her father was Dr. T. W. Jex-Blake, Dean of Wells and formerly headmaster of Rugby. After being headmistress of St. Margaret's, Polmont, from 1889 until 1909 she succeeded Dame Elizabeth Wordsworth, the first principal of the Hall, who had held office for thirty years.

The demand among women for an Oxford education had, throughout the Hall's history, led to a steady expansion in its numbers, and Miss Jex-Blake's term of office coincided with a marked increase in this demand. Under her a considerable building programme was carried out, in defiance of shortage of funds, and the Toynbee Building, designed by Sir Reginald Blomfield, was opened in 1914, bringing the accommodation for undergraduates up to eighty. Her principalship covered the difficult years of the First World War, and, following them, the culmination in 1920 of the long struggle for the opening of Oxford degrees to women. Miss Jex-Blake had the satisfaction of receiving the M.A. herself at the first degree ceremony in October 1920, and then of presenting a steady stream of her former students at successive ceremonies until her retirement in 1921.

In 1926 she was elected an honorary Fellow of the Hall. After her retirement she lived with her sister, formerly Mistress of Girton, first in London and then in Kent.

Miss Jex-Blake and her sisters had received an excellent education in the home under her father's care and was a good linguist, a highly accomplished musician and was widely read in the literature of several countries. She had travelled widely, particularly in France, Spain and Italy. She was in all her ways a lady of the old-fashioned kind, self-disciplined and imposing a high standard of conduct on herself and others. Though somewhat shy and reserved, she was most generous to those in need or trouble, and many members of the Hall owed much to her carefully concealed assistance. A graduate studentship at Lady Margaret Hall bearing her name has been formed from capital provided by her.

We regret to announce the following deaths:

Lieut.-General Sir William Furse, K.C.B., K.C.M.G., director of the Imperial Institute, London, during 1926–34, on May 31, aged eighty-eight.

Sir Thomas Hunter, K.B.E., emeritus principal of Victoria University College, Wellington, and vice-chancellor during 1929–47 of the University of New Zealand, aged seventy-six.

M. Camille Raveau, editing secretary of the *Comptes rendus* of the Paris Academy of Sciences during 1904–46 and known also for his work in the field of thermodynamics, on April 15, aged eighty-six.

NEWS and VIEWS

Applied Mathematics at Swansea: Prof. J. G. Oldroyd

Dr. J. G. Oldroyd has been appointed to the recently created chair in applied mathematics in the University College of Swansea. This post is within the Department of Mathematics, under the direction of Prof. R. Wilson, and the holder of the new chair will be responsible for teaching and research in applied mathematics in the College and will have his own staff for the purpose. Dr. Oldroyd has had a distinguished academic career. He was educated at the Bradford Grammar School and was a scholar of Trinity College, Cambridge. He was a Wrangler in 1941 and was awarded a distinction in Part III of the Mathematical Tripos in 1942; during this period he obtained the Rouse Ball, Mathison and Mayhew Prizes. In 1942 he entered the Projectile Development Establishment at Boncath, Cardiganshire, and remained there until 1945, when he joined the laboratory for fundamental research of Messrs. Courtaulds, Ltd., as a mathematical physicist. At their request he spent a year in research studies at Trinity College, Cambridge, and while still with Messrs. Courtaulds was elected to a research fellowship of Trinity College for the period 1947–51. He is honorary treasurer of the British Society of Rheology and of the Second International Congress on Rheology. He is also a member of the weapons research panel of the Ministry of Supply. His numerous publications relate to the theory of viscous flow, plastic flow and finite elastic deformation, especially in materials which have both viscous and elastic properties combined. His experience in these fields may be of help to the local industries at Swansea, which include the refining and circulation of oil products and the working of molten steel. Dr. Oldroyd's work will be of great interest to the Physical Science Departments and, in particular, to the Departments of Engineering and Metallurgy in the College.

New Nature Reserves in Britain

Following its declaration last summer as a national Nature reserve of 100 acres forming part of a small chalk coomb on the southern edge of the South Downs, some four miles north-west of Chichester, the Nature Conservancy has now added a further 100 acres to its Kingley Vale Nature Reserve, which nearly completes the acquisition of the natural yew woods, some of the trees of which are very old. About 76 acres, known as Mincing Wood and Crawford's Rough, of the extensive woodlands near Blean, Kent, have also been acquired by the Conservancy, and are being declared a national Nature reserve. The woods include sessile oak with hazel and hornbeam coppice, chestnut and birch, and contain a variety of unusual plants. The importance and value of the reserve are greatly increased by the presence of a species of butterfly, the heath fritillary, which occurs here and practically nowhere else in Britain, though its food plant (a semi-parasitic species) is well distributed elsewhere. Monk's Wood, about 375 acres of woodland, some five miles north-east of Huntingdon, has also been acquired and declared a Nature reserve. The area is the last of the few remaining examples of the ancient ash-oak woodland of the heavy Huntingdonshire clays, and is a classic locality for the characteristic fauna of such woodland, containing rare plants as well as rare insects. Although the wood was largely cut down during the First World War, natural regeneration has allowed the persistence of the most characteristic species. A further 84 acres, known as Barrow Wood, and part of the wood known as Hibbet's Wood, have been added to the 155 acres declared as the Ham Street Woods Reserve, Kent, in May 1952. This type of woodland—standards with coppice—is declining in this neighbourhood, and the Wild Life Conservation Special Committee recommended that samples of this type of woodland with its characteristic flora should be maintained to preserve the rich insect fauna, including species that seem to be disappearing or to have disappeared from other similar woods.

American Aid for Industrial and Technological Research in Britain

Arrangements for the expenditure of counterpart funds, amounting to nine million dollars, derived from the United States Economic Aid under

Section 9 (c) of the Mutual Security Act of 1952, are detailed in a Command Paper (Cmd. 8776; United States No. 1 (1953), dated February 25, 1953. London: H.M.S.O.; 6*d*.). The programme is based on the conclusion that there is need for wider knowledge throughout British industry of the best and most modern techniques and practices. It provides for the employment of technical advisers on re-organization and production techniques, who might be members of the staff of research or business organizations if they specialized in the problems of particular industries, or might work under contract for, say, the British Productivity Council or the Department of Scientific and Industrial Research, if they specialized in techniques applicable to the whole of industry. Expenditure for this purpose during two to three years is estimated at £457,000. A further sum, estimated at one million pounds during two or three years, is set aside for the expansion of research into factors affecting the efficiency of the national economy, including, for example, medical work on the design of machine controls and industrial fatigue problems; research into the sociology and social psychology of the relations between employer, management and employed; economic descriptive, statistical and theoretical work on the structure of industry; and the structure and practice of trade associations and trade unions. Such a programme would be carried out largely under contract by such bodies as the universities, economic or sociological institutes, the British Institute of Management and other professional and learned bodies. Further proposals include the promotion of studies in technological subjects at universities and technical colleges; the training of staff for courses for supervisors; and the provision of scholarships, including scholarships for trade unionists, in management subjects, part of which proposal might be a contribution by endowment to the building up, recently announced by the Government, of an institution of university rank devoted predominantly to the teaching and practice of technology. Expenditure of £178,000 on publicity for the programme is also proposed, and a revolving fund of £1 million for short-term loans to industry for equipment and reorganization and, for special purposes, to agriculture. The President of the Board of Trade will be generally responsible for co-ordinating the programme and for general policy.

British Journal of Animal Behaviour

THE study of animal behaviour, or comparative ethology, is attracting an impressive number of young students and probably stands in much the same position to-day as did genetics in the early days of this century and endocrinology in the decade following the First World War. The recent launching of a new quarterly, *The British Journal of Animal Behaviour* (1, No. 1; January 1953; obtainable from Baillière, Tindall and Cox, Ltd., 7–8 Henrietta Street, London, W.C.2), is therefore both timely and justified. The new *Journal* is the official organ of the Association (formerly Institute) for the Study of Animal Behaviour which was founded in 1936 and which, almost from the time of its inception, offered research grants for the study of ethology and published a small *Bulletin* which, issued at irregular intervals, has contained many admirable papers. The new quarterly replaces the *Bulletin* and will henceforward publish an increased number of contributions dealing with the physiology and psychology of behaviour of wild and domestic animals. The *Journal* is edited by Prof. A. N. Worden and Dr. B. A. Cross, assisted by a remarkably strong editorial board. It is pleasant to see on this the names of Julian Huxley and James Fisher, who, with F. B. Kirkman, were largely responsible for the formation of the Association. The first issue contains seven papers, five of which deal with the behaviour of vertebrates. There is a stimulating discussion on the term 'mimesis' by R. A. Hinde and E. A. Armstrong, and an editorial by Dr. W. H. Thorpe. It has to be admitted that this initial number is a little patchy in quality. One paper, largely composed of material taken from books and other papers, would have been better left out in favour of more original work. Further, there occur an unusual number of conspicuous misprints. These, however, are minor matters and need not be repeated in future volumes. One can predict with confidence that the new publication will quickly find its way into scientific libraries all over the world.

Aluminium Laboratories, Ltd.

AN increase in the research facilities of the aluminium industry is marked by the completion of the first stage of the extensions to the Banbury premises of Aluminium Laboratories, Ltd. The company, which is the research and engineering organization of the Aluminium, Ltd., Group, already has laboratories at Kingston and Arvida in Canada and a design office at Geneva, in addition to the Banbury laboratories which are adjacent to the plant of the associated company, Northern Aluminium Co., Ltd. The full scheme, to be completed by mid-1954, will increase the floor area threefold, and the present extensions have more than doubled the available accommodation by the addition of a large laboratory wing to the existing buildings and the erection of a new experimental block. This expansion of research facilities runs parallel with the Aluminium, Ltd., Group's development of productive capacity as typified by the Northern Aluminium Company's continuous strip mill at Rogerstone and by the expansion programme of the Aluminium Company of Canada, Ltd., at Kitimat, British Columbia. The new buildings were designed by Sir Percy Thomas and Son, and incorporate a number of novel features, including a central hollow wall running the whole length of the laboratory block, providing a vertical and uninterrupted duct on two floors in which all services are carried. Space heating is by aluminium panel ceilings with incorporated flush lighting and acoustical correction. Much use has been made of aluminium for windows, pitched roof trusses and coverings, partition framing, rainwater fittings, etc.

Lundy Field Society

THE sixth annual report of the Lundy Field Society is a record of continued progress, notably in ornithology. Of the 129 species of birds recorded in 1952, four were observed at Lundy for the first time. Among the rarer visitors were the little crake, the red-rumped swallow, the American robin, White's thrush and the red-headed bunting. During the year a study of ectoparasites on birds was begun and this work is being extended; the ectoparasites included *Ornithomyia fringillina*, which was found on the chiff-chaff and so adds another host to the already long list of hosts of the British species of *Ornithomyia*. Botanical investigations were designed to emphasize differences in the plant populations on the east and west coasts of Lundy and, from this preliminary work, two lines of research were undertaken to investigate the differences in the bracken (*Pteridium*) population on the two sides of the island and the plants associated with the thrift (*Armeria*) in the gullies of the west coast.

Royal Commission for the Exhibition of 1851: Awards for 1953

The Royal Commission for the Exhibition of 1851 has awarded senior studentships for 1953 (value £600 a year for two years) to the following for research as indicated: Miss M. P. V. Boarland (Bristol), organic chemistry at the Federal Technical College, Zurich; P. W. Higgs (London), theoretical physics at King's College, London; Dr. M. G. K. Menon (Bombay and Bristol), experimental physics at the University of Bristol; and J. C. Ritchie (Aberdeen), botany at the University of Manitoba and the Botanical Gardens, Montreal. The Commission has also awarded the following overseas scholarships for 1953 (value £450–500 a year for two years): Canada: R. G. Ackman (Dalhousie), organic chemistry at the Imperial College of Science and Technology, London; G. M. Graham (Dalhousie), physics at the University of Cambridge; and Miss M. M. Moodie (British Columbia), radiochemistry at the University of Cambridge. Australia: N. W. Tanner (Melbourne), physics at the University of Cambridge; and J. S. Turner (Sydney), physics at the Imperial College of Science and Technology, London. New Zealand: R. Hodges (New Zealand), organic chemistry at the University of Manchester. Republic of Ireland: Miss K. M. W. Gallagher (National University of Ireland), organic chemistry at the University of Bristol. Republic of India: S. Varadarajan (Delhi), organic chemistry at the University of Cambridge. Pakistan: F. H. Chowdhury (Dacca), chemistry at the University of Manchester.

Leverhulme Research Awards for 1953

The following have been awarded Leverhulme research fellowships, tenable for periods up to two years, for research as indicated: Dr. (Miss) D. Atkins (research worker), comparative studies of ciliary feeding mechanisms of Brachiopods and their allies; and Dr. E. R. Leach (reader in anthropology, University of London), study of traditional village organization among the Sinhalese of the Dry Zone of Ceylon. Leverhulme research grants have been awarded as follows: Dr. D. R. Arthur (lecturer in zoology, King's College, London), functional morphology of the genera *Ixodes* and *Dermacentor* in relation to their ecology; J. Bor (senior lecturer in physics, West Ham College of Technology), determination of the optical constants of metals and alloys; E. J. H. Corner (lecturer in botany, University of Cambridge), revision of the genus *Ficus* for the Flora Malesiana Foundation; W. F. Grimes (director, London Museum), petrology of implements of the Neolithic and Bronze Ages in Great Britain; Dr. G. Heslop-Harrison (lecturer in agricultural zoology, University of Durham), evolution and speciation of the Psyllidæ of Spain and Portugal; Dr. R. J. W. McLaughlin (demonstrator, University of Cambridge), differential thermal analysis of clay materials; D. P. MacPherson (community centre warden, Lanarkshire), Gaelic folklore from Vatersay and Isle of Barra sources; Dr. T. B. Reynoldson (senior lecturer in zoology, University College, Bangor), the taxonomy and ecology of pond and lake planarians; and Dr. A. J. Ward (lecturer in mathematics, University of Cambridge), general topology.

National Research Council of Canada: Scholarships and Fellowships in Science and Engineering

The National Research Council of Canada has granted 226 scholarships in science and engineering for 1953–54, totalling 224,000 dollars in value. These scholarships include 61 bursaries of 600 dollars each, 113 studentships worth 900 dollars, and 13 fellowships worth 1,200 dollars, nearly all of which are to be held in Canada. Special scholarships awarded for study outside Canada include seventeen awards of 1,500 dollars each, and seven awards worth 1,200 dollars each. These special scholarships are to be held in the following universities: eight at London, four at Cambridge, three at Oxford, two each at Birmingham and North Carolina, and one each at the Massachusetts Institute of Technology, and the universities of Chicago, Delaware, Pennsylvania and Wisconsin. One additional special scholarship worth 1,200 dollars has been awarded for study in Canada, at the University of Western Ontario. Fourteen overseas postdoctorate fellowships, each worth 2,500 dollars, have been granted for work at the following universities: three each at Oxford, Cambridge and London, and one each at the National Institute for Medical Research, and the universities of Birmingham, Leyden, Louvain and Uppsala.

Royal Meteorological Society: Officers for 1953–54

The officers and council for 1953–54 of the Royal Meteorological Society are as follows: *President*, Prof. O. G. Sutton; *Vice-Presidents*, Prof. P. R. Crowe, Sir Charles Normand, Mr. C. D. Ovey and Prof. P. A. Sheppard; *Vice-President for Canada*, Mr. F. W. Benum; *Vice-President for Scotland*, Dr. A. E. M. Geddes; *Treasurer*, Dr. J. S. Farquharson; *Secretaries*, Dr. H. L. Penman, Dr. G. D. Robinson (*Librarian*), Mr. R. G. Veryard and Dr. T. W. Wormell (*Editor*); *Council*, Mr. G. A. Bull, Mr. H. Charnock, Instr. Cdr. C. R. Darlington, Mrs. A. C. Douglas, Dr. A. G. Forsdyke, Dr. R. Frith, Dr. G. L. Hogben, Mr. R. E. Lacy, Mr. F. H. Ludlam, Mr. N. Pye and Dr. R. S. Scorer.

Sir Henry Wellcome Centenary Exhibition

To mark the centenary of the birth of Sir Henry Wellcome on August 21, 1853, a commemorative exhibition will be opened at the Wellcome Foundation, Ltd., on Wednesday, July 8, by Mr. Winthrop W. Aldrich, American Ambassador in London. This exhibition, which has been arranged and designed by the Wellcome Historical Medical Museum, will cover the whole period of Sir Henry's long life (1853–1936). The exhibits will range from interesting relics of his early days in the United States to sections on some of the world-famous research institutes which he established after he settled in Great Britain: the Wellcome Physiological Research Laboratories, Wellcome Chemical Research Laboratories, Wellcome Research Institution, Wellcome Museum of Medical Science, and Wellcome Historical Medical Museum and Library. It also deals with Wellcome's archæological expeditions to the Sudan and Palestine.

Symposium on Plasticity

A symposium on plasticity, the fourth of its kind, will be held at Brown University, Providence, R.I., during September 1–3, under the auspices of the University, the Engineering Mechanics Division of the American Society of Civil Engineers and the Office of Naval Research. The three principal topics to be discussed will be stress–strain relations (perfectly plastic, work-hardening, visco-elastic and visco-plastic materials); distribution of stress and strain in bodies exhibiting inelastic properties (static and dynamic problems, infinitesimal and finite deformations); and structural analysis and design in the inelastic range (limit analysis, static and dynamic loading, shakedown and inelastic buckling). The symposium is open to all. Further information can be obtained from Prof. H. J. Weiss, Graduate Division of Applied Mathematics, Brown University, Providence 12, R.I.

Announcements

It is announced from the University of London that Sir Roderic Hill, rector of the Imperial College of Science and Technology, has been elected vice-chancellor from September 1 for the university year 1953–54. Sir Alexander Carr-Saunders, director of the London School of Economics and Political Science, has been re-appointed deputy vice-chancellor for the university year 1953–54.

The following appointments have been made in the University of Sheffield: Dr. R. G. Wilkins, lecturer in chemistry; and Dr. N. M. Green, lecturer in biochemistry.

The Institute of Economic Engineering was founded in 1941, and is concerned with such topics as cost control, production planning and control, factory layout, methods engineering and work study, and incentives. These techniques are now becoming more widely known as industrial engineering, and the title of the Institute has accordingly been changed to the Society of Industrial Engineers. The offices of the Society are at 28 Victoria Street, London, S.W.1.

A residential conference on information service is being arranged by Aslib and will be held in the University of Nottingham during September 11–14. Communication problems, training for personnel in the field from different national aspects, methods of document copying, and administrative problems are among the topics to be discussed. Particulars can be obtained from the Director, Aslib, 4 Palace Gate, London, W.8.

A summer school in programme design for automatic digital computing machines will be held in the University Mathematical Laboratory, Cambridge, during September 22–October 2. The course, which will be along the same lines as those held previously, will give a basic training in the mathematical use of machines in general, dealing with the processes employed and their embodiment in programmes which specify the operation in detail, and lectures and practical classes will be held in the design of programmes for the Cambridge machine known as Edsac. Application forms (to be returned by July 18) and further information can be obtained from G. F. Hickson, Secretary of the Board of Extra-Mural Studies, Stuart House, Cambridge.

A joint meeting of the First and Second Commission of the Institut International du Froid will be held at the Federal Technical College, Zurich, during September 10–12. It will be under the auspices of the Institut für Kalorische Apparate und Kältetechnik der E.T.H. and the Physikalisch-Chemisches Institut of the University of Zurich, and will deal with the practical applications of very low temperatures: (1) gas separation by liquefaction, distillation, rectification and adsorption; (2) properties of materials used at low temperatures. Further information may be obtained from the Sekretariat, Institut für Kalorische Apparate und Kältetechnik, Eidg. Techn. Hochschule, Sonneggstrasse 3, Zurich.

The governing body of King's College, Cambridge, proposes shortly to award a fellowship intended to enable a man of proved distinction to undertake or complete a particular piece of work. While holding the fellowship, he would receive emoluments commensurate with his age and standing without the necessity of performing other specified duties. Further details can be obtained from the Provost of the College, to whom applications must be returned by October 1, 1953.

The trustees of the Plastics Industry Education Fund have recently provided a sum of £2,000 for the provision of scholarships, worth £125 a year for two years, and tenable at the Plastics Technology Department of the Borough Polytechnic, London, S.E.1, which will be open to young men already employed in the industry, or for boys leaving grammar and technical secondary schools. These scholarships, of which eight will be offered this year, will enable the holder to study for the diploma of the Plastics Institute, which is the preliminary step to the associateship of the Plastics Institute. They are only open to boys living in the United Kingdom who have reached the standard of the General Certificate of Education (ordinary level) in chemistry, physics and mathematics. Application should be made in the first instance to the Head of the Chemistry Department, Borough Polytechnic, Borough Road, London, S.E.1.

Because of the large increase in the number of papers received for publication in the *Australian Journal of Scientific Research*, Series A (Physical Sciences), the journal has been divided into the *Australian Journal of Chemistry* and the *Australian Journal of Physics*, each issued quarterly. The volume numbers continue from the earlier publication. The *Australian Journal of Biological Sciences* is the new title of the former *Australian Journal of Scientific Research*, Series B (Biological Sciences), and the publication of two new journals, the *Australian Journal of Botany* and the *Australian Journal of Zoology*, issued as material becomes available, is announced. All the journals are published by the Commonwealth Scientific and Industrial Research Organization, in collaboration with the Australian National Research Council.

The International Wool Secretariat has recently published a "World Wool Map", produced as a teaching aid by the Department of Education of the Secretariat. The map shows the wool-producing areas of the world with the numbers of sheep for 1950 and also the spinning areas and total production. A separate and more detailed map for the United Kingdom and Eire on the same sheet indicates also the characteristic breeds for the different districts and, besides the raw wool production, the total consumption of scoured wool in 1950 and the location of areas of consumption as woollen and worsteds, hosiery, carpets and felts. The sheet is obtainable from the Secretariat, Dorland House, 16–20 Regent Street, London, S.W.1, price 5*s*. per copy.

Erratum. In the article on "Synoptic Rocket Observations of the Upper Atmosphere" published in the issue of June 20, for "Prof. L. F. Bates" read "Prof. D. R. Bates" (p. 1109, col. 1, line 4).

COLLOID SCIENCE AND SOME OF ITS INDUSTRIAL APPLICATIONS*

By Dr. R. MATALON

Department of Physical Chemistry, King's College, London

It is undoubtedly true that fundamental research carried out in surface chemistry for more than forty years has now enabled technicians and engineers to find new and simpler methods for solving industrial problems as well as improving current processes in practically all fields: for example, textiles, metallurgy, cosmetics, drugs, paints and lubricants. In view of the importance of this growing field of science, some of the latest theoretical developments will be discussed with the object of encouraging applied research, using as a basis the fundamental approach that is now the subject of inquiry in the universities, and which, it may be hoped, will be taken up by other institutions conducting research in pure and applied science.

Considering first in its broadest sense orientated adsorption and its importance in determining colloidal behaviour, in which the pioneering work was done by Sir William Hardy, Lord Rayleigh and Devaux, the main factors are gaseous, liquid expanded, liquid condensed, viscous elastic and solid surface-films in relation to the molecular structure of the spread compound, to molecular packing, and to the cohesive forces such as are brought about by van der Waals forces, polar forces, hydrogen bonding and the like; the main observations on surface-films have been made with the Langmuir balance. The more recent approach is that of the school of Sir Eric Rideal on the study of reactions in surface-films: the extent to which the rate of reactions is affected by orientation and packing has been demonstrated by A. Hughes and Rideal for the oxidation of fatty acids, by A. E. Alexander for the hydrolysis of esters, and by J. H. Schulman and Hughes for the lypolysis by enzymes. In addition, molecular interaction in monolayers has been studied extensively by Rideal, Schulman, E. Stenhagen, E. G. Cockbain and R. Matalon.

The surface-film technique has indeed enabled the study of the reaction of tanning of proteins using tannic acid and phenols as well as polyvalent metallic ions such as ferric chloride. On the other hand, when the molecular interaction results in the 'penetration' of the solute molecules into the surface-film, a mixed structure of both components is observed. This type of interaction produces a solution complex or a stoichiometric association depending on the relative affinity of the interacting molecules. Penetration is observed at both the air/water and the oil/water interfaces. In the latter case, the relation between the surface pressures of the mixed film π_m and that of the single components π_1 and π_2, present alone at the same interface, may be exemplified for the system cholesterol – laurylsulphate. Whereas, as a general rule, the more surface-active component displaces from the surface the less active one, when penetration occurs the final surface pressure of the system exceeds that of any one of the single components π_1 and π_2, and in dilute systems $\pi_m = \pi_1 + \pi_2$. When the interacted mixed film is liquid, molecular interaction in bulk solution, as shown by Dervichian, results in the appearance of myelinic figures and tactoids.

There are a number of examples of the role of penetrated films in spontaneous emulsification. Thus the presence of a trace of a penetrating substance such as *iso*-octylalcohol in an alkylsulphonate greatly enhances the wetting of fibres and paper. The effect of adsorption on solids is illustrated by a simple experiment: copper chromate precipitated by the reaction of copper sulphate and potassium chromate is produced in the flocculated state when a trace of sodium oleate is added to the chromate. Finally, the periodicity observed in the Liesegang phenomenon is exemplified in the case of silver chromate, in which the adsorption complex gelatin – silver chromate is responsible for the periodicity observed.

Turning now to foams and the fundamental properties connected with foaming, the first requirement is that the molecules must rapidly diffuse from the bulk to the surface, the second that the adsorbed molecules must lead to a surface layer which is either condensed viscous or elastic, and the third that the surface layer must be somehow insolubilized—that is, showing a slow rate of desorption.

The traction apparatus developed by me shows the behaviour of surfaces on traction and retraction with saponins, proteins, beer and the synthetic surface-active agents. Saponins and proteins lead to an irreversible pattern on traction and retraction, whereas the alkylsulphate shows a reversible behaviour. Foaming may be done with anionic and cationic derivatives and also with non-ionics, as exemplified by the good foaming obtained with a condensate of heptylalcohol and six molecules of ethylene oxide. The part played by additives such as methylcellulose, alginic acid and polyvinyl alcohol in stabilizing the foam can be attributed to the more coherent structure obtained as a result of interaction with the foaming agent. There is a grave lack of quantitative work on the equally important field of defoaming. One of the important factors in defoaming is the displacement of a coherent surface layer by a compound, leading to a higher surface pressure and to a gaseous type of film. Defoaming of fermentation baths by the addition of alkylbenzenesulphonate is a direct example of this.

The useful applications of foaming in industry are manifold, as is indicated by the following selection: in fire-fighting; in food, such as in the manufacture of aerated chocolates, creams and meringues; in cosmetics, shampoos and washing powders; in building materials, such as porous concrete and light aggregates; and in the rubber industry, where porous rubber of both types may be obtained, those with isolated cells and with intercommunicating cells. On the other hand, the various instances where foaming is undesirable and combated are in the manufacture of photographic paper; in the course of distillation; in the working of lubricating oils; during fermentation; and in drilling muds.

---

* Substance of five lectures delivered at King's College, London, on January 13 and 27, February 10 and 24, and March 10.

Another aspect of colloids is that of emulsions, and the factors of importance in this colloidal state are: the emulsifier and its orientation at the interface; the mechanical properties of the interfacial film; its electrical properties; the relative density of the phases in contact; and the volume phase ratio. The role of the hydrophobic–hydrophilic balance of the emulsifier in determining the type of emulsion obtained is shown in the case of the ethylene oxide condensate with long-chain polar compounds. The nature of the oil must also be considered in relation to the emulsifier, and it can be shown that oleyl alcohol condensed with three ethylene oxide molecules leads to very good oil-in-water emulsions of spindle oil. For triolein, optimum emulsification is obtained with eight to ten molecules of ethylene oxide condensed on the oleyl alcohol. For oleic acid the emulsification is satisfactory with a condensate of fifteen molecules of ethylene oxide on the oleyl alcohol.

In considering the stability of the emulsion in relation to creaming and coalescence, the role of thickeners such as gums, clays, polyvinylalcohols in stabilizing emulsions is attributed to the effect of these materials in slowing down the creaming. Coalescence can now be studied directly by the traction curve of laminæ and by the life-time of droplets at the oil–water interface; the latter method has recently been developed by Cockbain and Roberts. In general, need for further study of emulsions lies in the importance of their role in industry, as, for example, in food for the manufacture of margarine, ice cream, mayonnaise, etc.; in textiles for the lubrication of yarn, the fulling of wool, sizing, mothproofing, etc.; the printing of cotton; the processing of leather; paints and distempers; polishes; insecticidal and fungicidal preparations; cutting-oils to aid the machining of metal, leading to higher cutting speeds and better finish of the surface; and the water–oil emulsions used for drilling muds.

Turning next to the phenomenon of wetting in colloids, the principles of wetting solids, the methods used for describing and studying this interesting property and finally the various applications of wettability in industrial practice must be considered. The measurement of the contact angle θ at the solid/liquid/air interface may be made by various techniques such as the capillary rise, the tilting plate and by direct observation using a microscope or any other magnifying equipment. The recent approach of J. Guastalla and his co-workers on the measurement of the adhesion tension is simple and entirely satisfactory for the study of wetting. The traction and retraction curve obtained with a solid plate makes it possible to determine the advancing and receding contact angle by direct applications of the formula $F = \gamma \cos \theta$ on a liquid surface of tension γ.

In the problem of dispersing and suspending solids, the important factors are particle size and adsorption at the interface of the added wetting agents and builders. Wetting agents find numerous and important applications in industry. Thus, in the pickling of metals, where the introduction of a wetting agent reduces the consumption of acid, loss of metal and processing time, a brighter surface is obtained. In electroplating, wetting agents prevent the adhesion of hydrogen bubbles, as well as control the structure of the deposit (for example, in bright nickel plating), and in the cleaning of metal they remove grease and dirt from surfaces. In soldering, a suitable wetting agent will enable spreading of the zinc chloride – ammonium chloride fluxes, and in the phosphating of steel 0·02 per cent dodecylbenzene sulphonate produces a uniformly treated layer. Phenolic bodies and short-chain alkylsulphonates ensure rapid mercerization of cotton, and wetting agents are good levelling agents in the dyeing of textiles; non-crystalline wetting agents, liquids or pastes, effect quick re-wetting of the textiles after drying. Other uses of wetting agents are in the extinguishing of fires, in accelerating reactions, such as the development of photographic films, and in the ethylation of cellulose, etc. Wetting and dispersion of solids play an important part in the manufacture of paints and varnishes, metallic soaps being here used for promoting wetting and quick dispersion of the pigments in the vehicle. Alkylbenzene and alkylnaphthalene are added in lubricating oils for the dispersion of carbon black. Finally, wetting agents play an important part in the processing of wettable powders used in medicine, in insecticides and in fungicides.

Dealing now with precipitation and growth regulation in supersaturated solutions and in precipitation reactions, a factor of importance is the metastability of the supersaturated system, which may be considered in parallel with the effect of mechanical shock, dust impurities or nuclei. The effect of interfacial forces in determining crystallization is exemplified in the overgrowth phenomenon, and excellent photographs obtained by Dr. M. Blackman and Mr. N. D. Liesegarten (Imperial College of Science and Technology, London) demonstrate the results obtained with potassium chloride, ammonium iodide, rubidium iodide and potassium bromide on mica.

Apart from the effect of the solvent in determining crystal habit, various additives, anionic or cationic, also play a part, as may be demonstrated by the effect of these surface-active agents on the crystal habit of succinic acid. Inhibitors of crystallization have been studied in the case of copper sulphate by A. Packter and myself, and our observations show that as a result of adsorption the time necessary for the appearance of the first visible crystals is increased, and that with increasing addition of inhibitor the crystal size first increases and then decreases again. The effect of sodium laurylsulphate in stratifying copper sulphate crystals is attributed to the adsorption on the copper ion of the long hydrocarbon chain, and the stratification of lead nitrate by agar is paralleled with the rhythmicity of the lead salts in agar.

The conditions affecting precipitation reactions are the primary factors of molecular ratio, concentration and temperature, and secondary factors of pH and other added reagents. The high degree of supersaturation observed in precipitation reactions is ascribed to precipitation complexes, such as $AgCl\ Ag^+$, $Ag_2CrO_4\ Ag^+$, etc. Precipitation inhibitors act by adsorption on to the precipitated sol and thus prevent crystal growth. Finally, the Liesegang phenomenon is a special case of precipitation reaction where adsorption on the precipitate is very pronounced. In general, the importance of controlling precipitation and growth of crystals is very great in the various applications of colloids, such as the preparation of stable sols in medicine, in the photographic industry, in electroplating, etc., and in the production of large crystals.

PHYSICAL SOCIETY

REPORT FOR 1952

AT the annual general meeting of the Physical Society, held at the Imperial College of Science and Technology, London, on May 15, the reports of the council and of the honorary treasurer and the accounts and balance sheet for 1952 were presented and adopted, and the officers and council for 1953–54 were elected (see *Nature*, May 30, p. 958). At the extraordinary general meeting held immediately after the annual general meeting, new articles of association and new rules of the Society, as approved by the Board of Trade, were finally approved and adopted. During 1952 the membership of the Society rose to 2,101—a net increase of seventy-six. The total income from subscriptions was £5,231; but this was less than the cost, £5,799, of providing the membership with the normal amenities and privileges. The new scheme of subscriptions, approved in principle in 1951, was adopted at an extraordinary general meeting held on October 3, 1952, and came into operation on January 1 this year. Under this scheme subscriptions for publications are separated from the subscriptions for membership, and thus the cost, £2,569, of providing members with *Physics Abstracts* during 1952 appears as an expense for the last time. In future the Society should be able to extend the amenities given to its Fellows. The thirty-sixth annual exhibition of scientific instruments and apparatus, held during April 3–8, 1952, was a great success with an attendance of thirteen thousand and resulted in a benefit to the Society of £4,000. This enabled the Society to finish the year with a balance of income over expenditure of approximately £2,500.

Eight science meetings were held in London during the year and two-day meetings at, respectively, the H. H. Wills Physical Laboratories, University of Bristol, at the University of Glasgow and at the Physical Laboratories, University of Manchester. The thirty-sixth Guthrie Lecture[1] was delivered by Sir Lawrence Bragg, who spoke on the X-ray analysis of proteins, and the sixth Rutherford Lecture[2] by Prof. R. E. Peierls, on the atomic nucleus and its constituents. Prof. L. Néel was the recipient of the seventh Holweck Medal of the Société Française de Physique and the Holweck Prize of the Physical Society; the presentation took place at the Royal Institution on May 27, when Prof. Néel delivered the Holweck Discourse[3] on the subject of antiferromagnetism and ferrimagnetism. The twenty-ninth Duddell Medal was presented to Mr. C. Waller, who gave a talk on some topics concerning the production and application of nuclear emulsions, and the eighth Charles Vernon Boys Prize to Dr. B. Bleaney, who spoke on paramagnetic resonance at low temperatures.

The Society continues to be represented on various joint committees and bodies, details of which are listed in the annual report, together with accounts of the activities of the four Groups of the Society, the Colour, Optical, Low Temperature and Acoustic Groups. In addition to science meetings, the Colour Group paid a summer visit to Cambridge, and the Low Temperature Group held its second overseas meeting early in November, when a party of twenty-four members visited laboratories and industrial plants in Holland.

The Society's Library has in the past been the joint responsibility of the Society and of the Institute of Physics, but the Board of the Institute has recently suggested that the Library would be better administered by the Society alone. It has presented to the Society all books and journals of the Institute at present in the Library and is continuing to pass on to the Library periodicals received in exchange for the Institute journals. The grant received during the year from the Royal Society for the development of the Library has been used mainly for cataloguing and for increasing the shelf space. This has been largely facilitated by the acquisition of a large council chamber at the Society's headquarters. A complete card-index to both text-books and periodicals is now available.

The average time of publication of papers in the Society's *Proceedings* has improved, so the report states, from five and a half months in 1951 to slightly less than five months in 1952, with the hope of still greater improvement in the near future. Both Sections *A* and *B* of the *Proceedings* contained about 115 papers each, but there were about twice as many "Letters to the Editor" in Section *A* as in *B*. The referees are again praised for their valuable services in keeping a careful check on the papers submitted for publication and for maintaining a high standard in content, style and composition. Of 295 papers and 141 letters submitted, approximately seventy were rejected as unsuitable for publication. Vol. 15 of "Reports on Progress in Physics", containing nine reports and a cumulative index of authors and contents of Vols. 1–15, was published during 1952, and Vol. 16 and a comprehensive cumulative subject index to Vols. 1–10 are in active preparation for publication this year.

INTERNATIONAL CO-OPERATION IN SCIENCE

THE report of a symposium on development of international co-operation in science held at Washington on October 18, 1951, in conjunction with the third annual meeting of the Executive Board of the International Council of Scientific Unions, has been issued by the National Academy of Sciences and the National Research Council (Development of International Cooperation in Science: a Symposium held in conjunction with the Third Annual Meeting of the Executive Board, International Council of Scientific Unions, October 18, 1951, Washington, D.C. Pp. 28. (Washington, D.C.: National Academy of Sciences/National Research Council, 1952)). It includes Prof. F. J. M. Stratton's brief review of the development of international co-operation in science during the past century down to the formation of the United Nations Educational, Scientific and Cultural Organization, and comments on the necessity which now confronts the Council and the Unions of either curtailing their activities or increasing their incomes; and the review of some international scientific joint ventures, for example, in publications, international surveys and laboratories, exchanges of scientists and the co-operative use of natural resources, made by Dr. W. A. Noyes, jun., in which he indicated some of the difficulties and the necessity of an open-minded approach to the problems, is also published.

Dr. J. N. Mukherjee described the attitude of Asia and the Far East, and Dr. C. J. Mackenzie, in putting

R 300

the Canadian point of view, referred to the importance of ensuring that representatives on the various bodies are chosen by scientists who are competent and knowledgeable about the work being done in all parts of the world. He believes that the existing organization is as good as any likely to be devised, provided the support of really first-class men is obtained and any moribund or inefficient parts that might develop in the organization are discarded. Dr. J. B. Koepfli's address, "Science and Foreign Relations", described the events leading to the creation in February 1951 of the Office of Science Adviser to the United States Department of State, and the way in which the activities of the Office are assisting international co-operation in science and encouraging international scientific organizations. The two main difficulties in its work, he thinks, are the administrative delays in the admission of foreign scientists into the United States and the legislative ceiling to the United States support of the International Council and the Scientific Unions. Scientists, he suggested, can help to overcome both these obstacles by fostering among themselves a fuller understanding of the United States' objectives and immigration laws, and by making the plans and work of the Council and its Unions more widely and fully known.

The address by Prof. A. von Muralt on international and national aspects of science directed attention to the importance of finding new ways of maintaining the atmosphere in which scientific development is best fostered, including new ways for arranging scientific congresses in view of the numbers attending, and new techniques for handling the dissemination and co-ordination of knowledge. While not over-rating the influence of scientific men, he believes that their efforts at international co-operation in science can contribute notably towards a wider understanding between all countries.

PHYSICAL APPLICATIONS OF HIGH-SPEED ROTATION

THE substance of a lecture entitled "Some Scientific Applications of High-Speed Rotation", delivered by Prof. P. B. Moon on April 27, 1951, to the South Wales Branch of the Institute of Physics, is printed as a special article in the *British Journal of Applied Physics* (4, 97; April 1953). First, brief reference is made to the familiar classical examples such as those to be found in the measurement of the velocity of light, the molecular pump and the centrifuge, and to the fundamental researches of Oliver Lodge (1897), where an attempt was made to 'drag' the ether by rotating disks, and of Blackett (1952), where the test was made, though unsuccessfully, to detect the magnetic field produced by a massive body rotating with the earth. The principles of rotor design are then discussed, and the best shape of rotor for attaining the highest practicable linear velocity at the periphery is considered. It is pointed out that, while the ideal shape is independent of the material and of the size, it is governed by the criterion of equal stress at all parts of the rotor. For a thin rod spinning about an axis perpendicular to its length, the ideal shape is that of a Gauss error-curve, and for a disk-like rotor the disk should be thin at the edge and the profile that of the Gauss error-function.

The various methods that have been used for driving rotors and their particular advantages and applications are next discussed. A detailed description is given of the particular method[1] introduced recently at the University of Birmingham, which Prof. Moon claims is nearly as simple as that of Colwell and Hall and nearly as effective as that of Beams. The rotor used consists of a doubly tapered steel rod with a small ball of hardened steel at its base. The ball runs on a glass plate, and an electromagnet suspended by a short thread to act as a conical pendulum supports and takes up about 90 per cent of the weight of the rotor. Peripheral speeds of up to 10^5 cm./sec. have been attained with a six-inch rotor. Various examples of such rotors are shown diagrammatically, and it is explained how the method has been applied at Birmingham to the production of high-speed beams of heavy atoms and molecules.

Rotating shutters for neutrons is the main application of rotational technique in the field of nuclear physics. Sectored disks of cadmium, which is highly opaque to very slow neutrons, were first used by Dunning and co-workers in 1935, but recent developments at the University of Chicago, as explained by Prof. Moon, have produced a 'sandwich' type of shutter composed of alternate layers of cadmium and aluminium enclosed in a strong steel shell which serves for the interruption of faster neutrons. Another shutter of this type consists of a slotted steel shaft rotating in front of a similar, coaxial, but fixed, shaft.

Finally, Prof. Moon's own particular application[2] of high-speed rotation in the field of nuclear physics is briefly described. A strong radioactive gold source of low mass is carried on the tip of a high-speed rotor, and by virtue of the Doppler effect sufficient energy is restored to the gamma radiation to produce resonant nuclear scattering in liquid mercury (10 per cent mercury-198).

THE MUTATION THEORY OF EVOLUTION

WHILE the majority of biologists agree that evolution proceeds by mutation and natural selection, Prof. L. P. Martin, of McGill University, suggests that the mutation–selection theory is not wholly convincing as a means of explaining natural evolution (*Amer. Sci.*, 41, No. 1; January 1953). This dissent is not so much due to a failure to master the facts as to the grasp of some facts which Martin believes geneticists are apt to overlook.

None of the facts, nor all of them together, establishes the mutation–selection theory beyond all doubt.

Among the difficulties raised by Martin and his fellow recusants is that, though the occurrence of mutations in both wild and domestic populations is clearly established and though they are important in the genesis of our domestic breeds of animals and plants, even giving rise to some disease-resisting strains, yet all mutations seem to be in the nature of injuries which, to some extent, impair the fertility and viability of the affected organisms. The impaired stamina of present-day domestic breeds is shown by their inability to survive in natural conditions, except in exceptional and sheltered environments. Resistance to disease conferred by some mutations seems to be illusory, for it is not a real or positive resistance but rather the removal of a host from an extremely narrow and specific range of susceptibility to a specific parasite. Lastly, the superior viability of a few mutations in an unusual environment is no evidence that they are not injuries, for injured organisms are sometimes more viable than normal ones in exceptional environments. In his experiments in 1944, for example, Leblond has shown that rats injured by thyroidectomy are more viable than normal rats in lowered oxygen pressures.

A truly progressive or 'beneficial' mutation must result in an improvement over the normal condition; but there is no clear evidence of the existence of such helpful mutations. In natural populations endless millions of small and great genic differences exist; but there is no evidence that they arose by mutation. All the available evidence tends to show that mutation is a pathological process which has had little or nothing to do with natural evolution, though mutations are extremely useful to man in his development of new domestic breeds. Nor is there convincing evidence that such a condition as a fully viable mutation ever occurs, while thousands of normal variations found in natural populations presumably arose by some as yet unknown and probably very subtle process; it is most unlikely that they arose by mutation.

While there is no doubt that species have evolved and that mutations and natural selection may be associated with the process, inferential evidence that the effects of long-continued over-use or disuse of a part can in time become hereditary is also impressive. Prof. Martin believes that the evidence for such inheritance is much stronger than is commonly realized, but that it is too often neglected or set aside from a mistaken notion that the mutation–selection theory offers a better established and less speculative explanation of all the known facts.

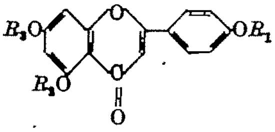
IDENTIFICATION OF FLAVONES BY THE ULTRA-VIOLET ABSORPTION SPECTRA OF THEIR IONS

By G. H. MANSFIELD*, Dr. T. SWAIN and C. G. NORDSTRÖM†

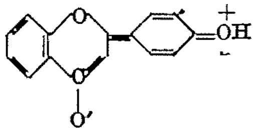
Low Temperature Station for Research in Biochemistry and Biophysics, University of Cambridge, and Department of Scientific and Industrial Research

It is well known that the ultra-violet absorption spectra of the ions of many polar-substituted compounds are markedly different from the spectra of the compounds themselves, usually the main band having shifted 20 mμ or more towards the red and increased in intensity. This fact has been used to a considerable extent in the study of the ionization of many weak acids and bases, including phenols[1]. However, so far as we are aware, no use has been made of these differences for identification purposes, although it is apparent from some of the data presented that certain polar compounds which have similar normal spectra may be differentiated by comparing the spectra of their ions (compare 4-*t*-butyl-2 : 6-dimethyl and 2 : 6-di-*t*-butyl-4-methyl phenol[1]).

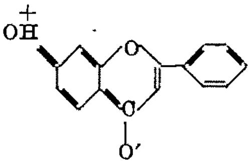
In the case of compounds, such as the flavones, containing a number of similar polar groups, each group will contribute to the total bathochromic shift on ionization, and if one or more is blocked (for example, by methylation or glycosidation) the resulting shift should be substantially different. Since it has been shown that, except for flavonols and their 3-glycosides, the normal ultra-violet spectra of most flavone and flavonol glycosides are similar to those of the parent aglycone[2], it was felt that the spectra of the ions might afford an elegant method of differentiating such compounds which had been obtained in too small a quantity (for example, separation by paper chromatography[3,4]) for the normal chemical methods to be applied. From the results obtained, it is evident that the position of attachment of sugar in flavone glycosides can be determined from the spectra of the ions of either the compounds themselves, or the partial methyl ether of the corresponding aglycone obtained from them on a micro scale[4] by methylation and subsequent hydrolysis.



(I)



(II)



(III)

The solubility of flavones in various alkaline media has been studied by Briggs and Looker[5], and it was apparent from their results and those of Coggeshall and Glessner[1] that the greatest differentiation of the spectra of the ions would be obtained at an alkali concentration below which complete ionization of all the phenolic hydroxyl groups took place. Although we have not as yet examined this point critically, we have found that 0·002 *M* sodium ethoxide in absolute ethanol is a suitable medium. The normal spectrum of the compound was first determined in absolute ethanol (2·5 ml.) using 1-cm. cells in a Hilger 'Uvispec' spectrophotometer over the range 220–450 mμ at 10-mμ intervals. Sodium ethoxide solution (0·5 ml. 0·012 *M*) was then added and the spectrum of the ion determined over the same wavelength interval. No attempt was made to determine accurately the position of the absorption maxima and minima or the molar extinction coefficient (ε), since the method has been envisaged specifically as a diagnostic one, and therefore devised to be as simple as possible in operation; but the spectra of the compounds themselves agree well enough with the published data[6] both in position and relative ε values of the absorption maxima. The $\lambda_{max.}$ quoted in Table 1 were obtained by interpolation, and the optical densities (*D*) are given as a percentage of

A consideration of the spectra of more than forty synthetic free and partially methylated flavones and flavonols has shown many interesting regularities, the most notable of which is the difference in the contribution to the alkali shift made by the 5-, 7-, and 4′-hydroxyl groups in the flavone nucleus. These differences may best be illustrated by reference to apigenin (5 : 7 : 4′-trihydroxyflavone; formula I, R_1, R_2, R_3 = H) and its derivatives (see Table 1 and graphs). The normal spectra of apigenin and its 5 : 7-, 5 : 4′- and 7 : 4′-dimethyl ethers (formula I, R_1 = H, R_2, R_3 = Me; R_2 = H, R_1, R_3 = Me; R_3 = H, R_1, R_2 = Me) are similar. The spectral shift of the dimethyl ethers in alkali is notably different both in amount (Δλ) and in relative intensity (Δ*D* per cent). For band I (c. 330 mμ), the 5 : 7-dimethyl ether has the largest shift (Δλ = 53 mμ) and the intensity of the band is also increased (Δ*D* per cent = 48), whereas with the 5 : 4′-dimethyl ether, although the spectrum shows a distinct change, the shift is less (Δλ = 34 mμ) and the band has a reduced intensity (Δ*D* per cent = − 32). For the 7 : 4′-dimethyl ether, band I is almost completely suppressed, possibly due to the strong hydrogen bonding of the 5-hydroxyl group with the neighbouring oxygen at C_4, as manifested by difficulty of methylation and paper chromatographic studies[8]. For band II (c. 270 mμ) the 5 : 7- and 5 : 4′-dimethyl ether have the opposite behaviour to that shown for band I, the former compound having a relatively small shift and reduced intensity, whereas the latter has a larger shift and greatly increased intensity. The 7 : 4′-dimethyl ether has an even larger shift than the 5 : 4′-ether, but in this case the increase in intensity is much smaller (Table 2). The differences between the changes in band I for the compound having a free 4′-hydroxyl group and that having a free 7-group is probably due to the extended conjugation of the former as shown by formulæ II and III, and is given by all the compounds we have studied.

The spectra of two apigenin monoglucosides have also been compared. The first was obtained from the partial hydrolysis of apiin, purified by paper chromatography[4], and is undoubtedly the 7-glucoside (formula I, R_1 = glucosyl; R_2, R_3 = H). The second was obtained from the petals of a variety of *Dahlia variabilis*[5] and appears to be 4′-glucosylapigenin (formula I, R = glucosyl, R_2, R_3 = H). These compounds had different R_F values (7-, 0·56; 4′-, 0·52) in butanol–water, and the 7-glucoside had a distinctly more yellow fluorescence than the 4′-compound in ultra-violet light when fumed with ammonia. The spectra obtained from these compounds (see Table 1 and graphs) show that they exhibit similar behaviour to the corresponding dimethyl ethers. The differences in alkali shift ($\Delta\lambda$) and relative intensities (ΔD per cent) are, however, not so great as with the ethers but follow the same order (Table 2). Nevertheless, it can be seen from the graphs that the two glucosides are readily distinguished by the spectra of their ions in sodium ethoxide solution.

Similar effects have been obtained with other glycosides, and these results and application of the method to reflectance-spectra on filter paper will be published in full elsewhere.

We wish to thank Dr. T. H. Simpson, of the Torry Research Station, Aberdeen, and Dr. W. D. Ollis, University of Bristol, for gifts of synthetic and natural flavone derivatives. We also wish to thank Dr. T. White, the Forestal Central Laboratory, Harpenden, for his helpful advice.

The work described in this paper was carried out as part of the programme of the Food Investigation Organization of the Department of Scientific and Industrial Research. [Nov. 18.

LIGNIN CHEMISTRY AND THE TAXONOMY OF HIGHER PLANTS

By G. H. N. TOWERS* and PROF. R. DARNLEY GIBBS

McGill University, Montreal

IT has been known for more than fifty years[1] that the woods of dicotyledons in general give a positive Mäule reaction (a rose-red colour when treated successively with aqueous potassium permanganate, hydrochloric acid and ammonia), while those of conifers in general give a negative test (a brownish or orange colour without a trace of red). In 1941 or 1942 a chance remark by the late Dr. Harold Hibbert, that following alkaline nitrobenzene oxidation he was getting syringaldehyde and vanillin from the lignin of maple but vanillin only from that of spruce, led one of us (R. D. G.) to suggest that a positive Mäule reaction is due to the presence of the syringyl group. (We learned later that Campbell *et al.*[2–4] had shown that the chlorine–sodium sulphite colour reaction of woody tissues seems to be due to a syringyl or similar grouping.) This suggestion was followed up and the results of these investigations published by Creighton, Gibbs and Hibbert in 1944[5]. A wide selection of vascular plants were tested by the Mäule technique and more than fifty selected species were then subjected to alkaline nitrobenzene oxidation. The aldehydes were separated by fractional sublimation. In each case it was possible to isolate syringaldehyde and vanillin from species giving a positive Mäule reaction, while vanillin only was obtained from those giving a negative reaction.

Dicotyledons in general gave syringaldehyde/vanillin (S/V) values of about 3, but there were interesting exceptions. Thus the lignins of the supposedly primitive dicotyledons *Belliolum haplopus* and *Zygogynum vieillardi* gave values of little more than 1. Conifers in general, negative to Mäule's test, yielded no syringaldehyde; but about a dozen species of *Podocarpus* gave faint to strong positive Mäule tests (Crocker[6] had previously found one species of *Podocarpus* to give a positive Mäule test), and those giving a strong positive reaction had S/V values of about 1. Particularly interesting was the case of *Tetraclinis articulata*. This monotypic genus of the Cupressaceae, separated by Masters[7] from *Widdringtonia* and *Callitris* by 'traditional' taxonomic methods, was found to be sharply set aside from other members of the Cupressaceae in that it gave a strong positive Mäule test and an S/V value of 0·8. Masters's separation was thus upheld by chemical analysis, and one of us (R. D. G.) has brought together other chemical evidence pointing in the same direction[8]. The three genera of the Gnetales (*Ephedra*, *Welwitschia* and *Gnetum*) were also found to give positive Mäule tests —extending the findings of Schindler[9]—and to yield both syringaldehyde and vanillin. Monocotyledons gave both syringaldehyde and vanillin (and gave a positive Mäule test), while three species yielded also some *p*-hydroxybenzaldehyde.

The results of these investigations appeared in 1944, but it was clear that further work on the possible application of lignin analyses to taxonomy was desirable. In the first place, it seemed worth while to determine whether or not *p*-hydroxybenzaldehyde is restricted to monocotyledons (and among them perhaps to grasses) as the results (in ref. 5) might suggest; to see if all the supposedly primitive dicotyledons have low S/V values; and to look for unusual or suggestive ratios which might throw light upon plant relationships. The method used by Creighton *et al.* is slow and requires rather large amounts of plant material (about 50 gm.). It was therefore of the greatest interest to learn from Stone (to whom our thanks are due) of a new micromethod using paper chromatography to separate and estimate the aldehydes resulting from the alkaline nitrobenzene oxidation of small amounts (40–100 mgm.) of woody material. A description of the method, used in the present work, has now been published by Stone and Blundell[10].

Qualitative results are summarized in Table 1. It is obvious that *p*-hydroxybenzaldehyde is far from restricted in its occurrence. It has been found in *Psilotum*, in several lycopsids, in *Equisetum*, in a fern, in a cycad, in several conifers, and in all the monocotyledons examined. It appears to be absent, in general, from dicotyledons (present in *Tetracentron sinense* but absent from its probable relative *Trochodendron*). In *Isoëtes* there seems to be a lack of

correlation as between the Mäule test and the presence of syringaldehyde; but lignin quantities here are small, and careful reinvestigation would seem to be desirable.

Since results from 'primitive' dicotyledons are disappointingly variable, further work is required, and one of us (R. D. G.) is investigating other aspects of the chemistry of the Magnoliales (in the sense of Gundersen[11]), an order which includes these plants.

As an example of the 'unusual or suggestive ratios' referred to above we may take those met with in the Aceraceae. This relatively small family is usually considered to have but two genera: *Acer* (Tourn.) L. with perhaps 150 spp., and *Dipteronia* Oliv. with 2 spp. A third genus, *Negundo* Moench, is sometimes 'made' to include about four of the species of *Acer*.

To date we have accumulated data pertaining to about one-third of the known species of *Acer* (including the *Negundo* group) and to the two species of *Dipteronia*. Data obtained include S/V ratios (19 spp.); 'quantitative' Mäule tests (29 spp.); reaction with the hydrochloric acid/methanol reagent of Isenberg and Buchanan[12] which seems to indicate catechol tannins[13] (51 spp.); reaction to Gorter's test[14] which is supposed to indicate caffeic and/or chlorogenic acid(s) (16 spp.); presence or absence of quebrachitol as recorded by Plouvier[15] (6 spp.); and iron and manganese values as determined by Riou and Delorme[16] (6 spp.).

We find that S/V values are usually high in *Acer* proper (averaging 2·0 for 14 spp.); low in the *Negundo* group (0·5 for *A. cissifolium* and *A. negundo*, 0·6 for *A. henryi*) and in *Dipteronia* (1·0 in *D. dyeriana*, 0·3 in *D. sinensis*). 'Quantitative' Mäule tests (in which depth of colour from weak to strong is indicated by values 1 to 3) roughly parallel the S/V values. Most true maples give a strong hydrochloric acid/methanol reaction, while the *Negundo* group gives no, or a very weak, reaction. *Dipteronia* gives a deep colour with this reagent. The results from Gorter's test suggest that the family as a whole lacks caffeic and/or chlorogenic acid(s), while Plouvier's observations indicate the probable general occurrence of quebrachitol. Finally, we have learned that Riou and Delorme have found that *Acer negundo* differs strikingly in manganese content and slightly in iron content from our five local species of *Acer* (Table 2).

We believe that the *Negundo* group differs sufficiently from the other species of *Acer* to be set aside from them, thus reviving Moench's old genus *Negundo*. Further work, which is proceeding, may determine if this separation is justified.

Our thanks are due to Andrew Taussig, Brian Goodwin and Arthur Dawson for assistance with the lignin analyses, to the National Research Council of Canada for financial assistance, and to the many friends who have provided us with samples for our investigations. [Feb. 26.

Structure of Insulin as indicated by Atomic Models

THE molecule of insulin consists of polypeptide chains of two kinds linked together by cystine residues. The complete amino sequence in these chains is now known, thanks to the work of Sanger and his co-workers[1]. The *A* chains of Sanger's acid fraction contain twenty-one residues and the *B* chain thirty residues. There are four half-cystine residues in the *A* chains and two in each of the *B* chains, and their positions in the residue sequence are *A*6, *A*7, *A*11, *A*20 and *B*7, *B*19. The minimum molecular weight has generally been reported to be about 12,000; but recently a value of the order of 6,000 has also been put forward. If the former value is correct, there will be two *A* and two *B* chains in the molecule, while there can only be one of each if the latter value is confirmed. It follows that if the linking arrangement could be determined, the complete chemical structure of this protein molecule would be known. There are many conceivable ways of linking the chains together and in the case of four chains there are some hundreds. It would be a considerable advance towards determining the complete structure if all those which are sterically impossible could be eliminated.

In what follows, we shall describe all the structures based on the Pauling 3·7 residue helix (thirteen-membered ring)[2] which have been found sterically possible as the result of using suitably constructed space-filling atomic models[3]. In deducing these structures, all possible combinations of left- and right-hand helices were considered. Since the polypeptide fold in this molecule may be something other than the Pauling helix, it is possible that not one of these structures is the correct one for insulin; but at least the field for further investigation has been considerably reduced.

When arranging the models, the helices were only allowed to bend to the small extent which was possible without breaking hydrogen bonds. It was found that no intra-chain link could be formed. Since an intra-chain link would have to be formed in any two-chain structure, it follows that either the two-chain structure is impossible or that the Pauling helix cannot be the basis of the structure. It remained, therefore, to investigate the four-chain structures.

It was shown that three links could not be formed between the two *A* chains. Some structures in which each *B* chain could be linked to both *A* chains could be built, but none of these allowed the chains to lie parallel (as indicated by the X-ray evidence[4]) or the molecule to take up a planar configuration (surface chemistry evidence points to a molecule 7–9 A. thick[5], which is much less than the thickness of two helices) and were not, therefore, further considered.

There remain those arrangements in which each *B* chain is attached by two links to one *A* chain. Each half of the molecule will contain one *A* and one *B* chain, and we shall first discuss how these can be linked together. It was found impossible to form the two links between an *A* and a *B* chain if one chain was wound into a left-hand helix and the other into a right. Therefore the half-molecule must contain *like* helices (both left-handed or both right-handed). There are then six possibilities of constructing half-molecules in which the links are: (1) *B*7–*A*7, *B*19–*A*20; (2) *B*7–*A*20, *B*19–*A*7; (3) *B*7–*A*11, *B*19–*A*20; (4) *B*7–*A*20, *B*19–*A*11; (5) *B*7–*A*6, *B*19–*A*20; and (6) *B*7–*A*20, *B*19–*A*6. With the first four of these arrangements, however, attachment to another half-molecule was found sterically impossible, so that it would seem that the acceptable structures must be based on the half-molecules (5) or (6), or a combination of the two (in the half-molecule (5) the chains are parallel, whereas in (6) they are anti-parallel). By combining these half-molecules in all possible ways, we obtain six molecular structures in which the four helices are all right- or all left-handed, and six in which one half-molecule has left-hand helices and the other right-hand helices. These are shown in the diagram, where the numbers refer to the positions of the half-cystines in the residue sequence. Opposite 'helix arrangement' is given the kind of helix (*L* or *R* for left- or right-hand) and the arrangement of the helices (‖ or × indicating whether the adjacent helices are parallel or anti-parallel to one another). It was found possible to build all these six structures and attach all the side-chains in the correct sequence.

The third residue from the end of each *B* chain is a proline residue. It was found that this will fit on to a right-hand helix, but calls for a re-arrangement of neighbouring parts of the chain before it can be fitted to a left-hand helix. (The convention used in building the model corresponded to what is now known to be the absolute configuration of an L-polypeptide[6]. With a D-polypeptide the proline would fit a left-hand helix.) Riley and Arndt[7] have suggested that this might be decisive in making the *B* chain a right-hand helix. Since we have shown with the models that the two helices in a half-molecule must be either both right- or both left-handed, it would follow from their suggestion that all four chains in the molecule could only be right-hand helices, and the possible structures would be reduced to six. It is, however, far from certain that one proline residue so near the end of the chain could be decisive in this respect.

	I	II	III	IV	V	VI
Overall length: Residues	30	43	30	33	35	38
Overall length: Angstroms	44	63	44	48·5	51·5	56
Helix arrangement	L ‖ L ‖ L ‖ L	L ‖ LXL ‖ L	LXL ‖ LXL	LXLXLXL	L ‖ L ‖ LXL	L ‖ LXLXL
Helix arrangement	L ‖ L ‖ R ‖ R	L ‖ LXR ‖ R	LXL ‖ RXR	LXLXRXR	L ‖ L ‖ RXR	L ‖ LXRXR

It was shown that all twelve structures could be pulled into a β-configuration of four fully extended chains,[2] which was consistent with the finding that insulin could, at least in part, undergo a reversible $\alpha \rightleftharpoons \beta$ transformation[3]. To demonstrate this convincingly with so large a molecule, it was necessary to concentrate attention on the small ring which includes the two *A*7 and two *A*11 half-cystine residues.

Finally, it was also found possible to show that each of these structures could be fitted into the unit cell deduced by Barbara Low[4] for acid insulin sulphate, so as to be consistent with the symmetry requirements. Particulars of this will be published elsewhere in a more detailed account of this investigation.

Thanks are due to Dr. C. H. Bamford and Dr. H. Tompa for their advice on relating the structures to the unit cell, and to Mr. J. E. Goodwin for his assistance with the building and manipulation of the models.

Polysaccharides associated with Alpha-Cellulose

ALPHA-CELLULOSE is an insoluble fibrous residue obtained by extraction of wood, straw pulps and holocelluloses with strong alkali under carefully controlled conditions. Since the procedures used are arbitrary, the yield and composition of the alpha-cellulose prepared from any specific source may vary within rather narrow limits. Although alpha-cellulose from structural celluloses consists largely of β-1,4 glucopyranose chains, it contains also some non-glucose units. Xylan appears to be associated with most alpha-celluloses, with mannan being present also in those from gymnosperms[1,2]. Recent evidence by Leech[3] indicates that a chemical union exists between the glucose and mannose units. Analytical data on wood alpha-celluloses suggest that uronic acid residues are also contained in the alpha-cellulose fraction, although positive identification of the specific acid has not been made[2].

Chromatographic methods for the separation of sugars provide an excellent means of examining the polysaccharides associated with alpha-celluloses. Our observation that 'xylan' of wheat straw has L-arabinose and D-glucuronic acid units attached to the xylan chain[4,5] led to investigation of the 'xylan' material in various alpha-celluloses prepared from cereal straw holocellulose and wood pulps.

Extractive-free wheat, oat and barley straw and jute fibre were converted to holocellulose by treatment with acid chlorite[6]. Alpha-cellulose was prepared from these holocelluloses, and from purified cotton linters and wood pulps (hardwood and softwood) by the standard 17·5 per cent alkali treatment[7]. 1-gm. samples of each of the alpha-celluloses were hydrolysed according to the usual Klason lignin analysis procedure[8]. Removal of acid with barium carbonate provided solutions of the simple sugars produced by hydrolysis. Glucose was oxidized preferentially by incubation for 18 hr. with 'Deoxygenase' (a commercial glucose oxidase preparation). The solutions were clarified by centrifuging and concentrated to a small volume. Paper chromatography of the sugar solutions after removal of the glucose permitted small amounts of other sugars to be readily detected. Removal of inorganic salts (introduced as buffers in the enzymatic oxidation) by ion exchange resins was required before chromatography of the sugars only in the cases of the wood pulps. The results of quantitative chromatographic analysis are given in the accompanying table.

COMPOSITION OF ALPHA-CELLULOSE

Sample	D-Xylose (%)	L-Arabinose (%)	D-Mannose (%)	Uronic acid anhydride (%) (CO$_2$ × 4)
Sulphite pulp (softwood)	0·47	nil	1·30	1·32
Sulphite pulp (hardwood)	0·33	0·08	nil	1·00
Wheat straw	5·48	3·27	nil	2·52
Jute straw	5·53	4·19	nil	3·68
Barley straw	3·86	5·79	nil	3·34
Oat straw	1·86	4·71	nil	3·20
Cotton fibre	nil	nil	nil	1·34

Both D-xylose and L-arabinose were found in the hydrolysates of cereal straw alpha-celluloses. So far as we are aware, the presence of L-arabinose in alpha-cellulose hydrolysates has not been reported previously. In barley and oat alpha-cellulose, the L-arabinose content exceeded that of D-xylose. The finding of pentosan material in the alpha-cellulose from jute chlorite holocellulose is contrary to the results reported by Sarkar, Mazumdar and Pal[9]. Since these workers did not remove D-glucose prior to chromatographing their solutions, the small amounts of other sugars were probably obscured. L-Arabinose units were detected in the alpha-cellulose of hardwood pulp, but no D-mannose was found. The softwood pulp alpha-cellulose yielded both D-mannose and D-xylose, in agreement with the observations of Lewis *et al.*[1]. The acid conditions used for preparation of the wood sulphite pulps may account in part for the relatively small amount of pentose sugars found in their alpha-celluloses. Cotton alpha-cellulose, which is a β-1,4 polyglucosan, yielded only D-glucose.

The presence of uronic acid in alpha-cellulose of straws and jute is suggested from the analytical data shown in the table. The naphthoresorcinol test on the hydrolysates was positive, although no uronic acid could be detected on the chromatograms. Proof of the presence of uronic acid units must await more rigorous methods of identification. Cotton and the pulp alpha-celluloses are considered free from uronic acids. The presence of L-arabinose in addition to D-xylose, and the possible presence of uronic acid units, suggest that the same polyuronide hemicellulose found in wheat straw holocellulose[4] may be associated with straw alpha-celluloses.

Whether the non-glucose constituents found in alpha-cellulose are chemically joined to the cellulose molecule or are only physically associated as envisaged in the cellulosan of Hawley and Norman[10] is not known.

We wish to thank the following commercial organizations: Industrial Cellulose Research, Ltd., Hawkesbury, Ontario, for the wood pulps; Indian Jute Mills Association, Baltic House, London, England, for supply of a sample of jute; and Takamine Laboratory, Clifton, New Jersey, for a generous sample of 'Deoxygenase'.

Action of Thionyl Chloride on Carboxylic Acids in Presence of Pyridine

IN order to use thionyl chloride most effectively for the preparation of acyl chloride, *R*CO.Cl, a knowledge of the sequence of reactions occurring is desirable. Trichloroacetic acid reacts extremely slowly with thionyl chloride even at higher temperatures; but Carré and Libermann[1] have shown that pyridine (1 mol.) helps the reaction. Mills and Human[2] adopted the use of the base in the preparation of anilides and esters of the half-esters of phthalic acid. We have now shown that during the addition of the first half of the thionyl chloride (1 mol.) to an ethereal solution of *cyclo*hexyl hydrogen phthalate (1 mol.) and pyridine (1 mol.), the following reactions occur:

$$R.CO_2H,NC_5H_5 + SOCl_2 \rightarrow R.COCl + C_5H_5NHOSOCl$$
$$R.CO_2H,NC_5H_5 + R.COCl \rightarrow (R.CO)_2O + C_5H_5NHCl$$

The second half of the thionyl chloride then converts the anhydride into the acyl chloride, and it was from the latter that Mills and Human obtained the anilide by adding the amine together with pyridine. Now the significant point is that although the formation of anhydride is very rapid[3], the formation of acyl chloride from the anhydride is comparatively slow and requires a time which depends on the nature of *R* in the acyl group. It just happens that the anhydride of *cyclo*hexyl hydrogen phthalate (the example quoted by Mills and Human) will give acyl chloride in yields approaching 80 per cent in the one hour of reaction time allowed by these workers; but the rate of formation of acyl chloride from the anhydride of 2-octyl hydrogen phthalate is definitely slower, and we were at a loss to account for the high yield of anilide reported by Mills and Human.

It appeared possible that the anhydride itself was giving the anilide; but in this case this reaction would have to compete with a very quick interaction of the amine with thionyl chloride remaining.

Trichloroacetic acid is a special case[1]. The acyl chloride is formed directly from the acid by the addition of thionyl chloride (1 mol.) to the acid (1 mol.) and pyridine (1 mol.), and the acyl chloride does not react with the acid to give the anhydride.

Use of the Warburg Apparatus in Soil Metabolism Studies

METHODS so far used for studying the evolution of carbon dioxide resulting from the decomposition of soil organic matter[1], although satisfactory for periods of 24 hr. or more, do not permit measurements for shorter periods, which may be important in studying the immediate effects of soil treatments.

It seemed that the Warburg respirometer had possibilities in this regard. Other workers[2] have, in fact, used it to study the respiration of suspensions of non-soil organisms added with excess substrate to soils at various moisture-levels, in order to assess aeration conditions in the soil. In these studies, however, the respiration of the soil population itself was not closely followed, and no attempt was made to relate respiration to the decomposition of soil organic matter.

The application of the Warburg apparatus to the study of soil metabolism has the particular advantages that respiration can be accurately measured over short periods, respiratory quotients obtained and the immediate effects of substrate or inhibitor studied by addition from the side arm of flask.

Although the purpose of the present communication is chiefly to direct attention to its possibilities, it is of interest to note some points that have become apparent.

Table 1. RESPONSES OF THE SOIL POPULATION TO AMELIORATION

Soil	Gas	Microlitres of gas per gm. of soil after 1	2	3	4	5	6	7 hr
(a) Untreated soil	O_2	9	21	34	46	58	72	86
pH 4 8	CO_2	8	20	33	47	60	75	89
(b) Soil with $Ca(OH)_2$	O_2	15	26	40	52	72	88	105
to pH 6 7	CO_2	17	30	45	57	73	88	102

The soil from which the results in Table 1 were obtained had been stored in an air-dry condition for ten weeks before use, and respiration studies commenced within an hour of wetting. It is interesting to note the short duration of any lag period in the development of respiration. Note, too, the immediate increase in respiration-rate on raising the *p*H with calcium hydroxide. Both results suggest the existence of a soil population in a relatively resting or inhibited state, able to respond without significant multiplication or adaptation to improved moisture or *p*H relationships.

Subsequent decline in the respiration-rate after several days with moisture-level constant suggests that some part of the soil organic matter is in a more readily decomposable form after the soil has been air-dry for a period.

Table 2. EFFECT OF MOISTURE CONTENT ON RESPIRATION

Moisture content of soil	Respiration (µl.) after 3 hr. Oxygen uptake	Carbon dioxide evolved	R.Q.
100%—saturated	22	72	3·1
60% (water holding capacity)	145	147	1·0
48% (field capacity)	125	100	0·8
24%	65	60	0·9
5% (air-dry)	0	0	

Table 2 shows that the activity of the soil micro-organisms in this sample of soil was at a maximum above field capacity but was less in the saturated soil. Webley[3], using yeast cells suspended on soils of different moisture-content, found a similar decline in respiration above an optimum moisture-level, and demonstrated that this was due to a reduction in the availability of oxygen. The results obtained indicate a similar behaviour by the normal soil population, and there is a relationship between soil moisture and overall metabolism as indicated by the respiratory quotient.

The effect of particular added substrates can also be investigated by this method. A more detailed account will be published elsewhere.

A Microgasometric Procedure

IN experiments now being carried out on the X-ray induced decomposition of azides, we have found it necessary to develop a simple method for measuring small volumes of gas (of the order of several cubic millimetres) evolved when a crystal (generally weighing one or two milligrams) dissolves in water. The method may have applications to other problems.

One or two square cover-slips are cemented on to each end of a microscope-slide so as to form raised steps. A thin glass plate (this should be thicker than a cover-slip, in order to prevent bending under surface-tension forces) can be placed across these steps, so that a narrow space (0·3 mm. thick in our apparatus) is left between it and the central part of the microscope slide. The solid sample is placed in the middle of this central area and covered with the glass plate. From a pipette a quantity of water, pre-determined to be just sufficient to fill the space between the slide and the glass plate, is then squirted quickly into this space. The space fills before any appreciable amount of the sample dissolves. As dissolution takes place, the evolved gas forms bubbles between the slide and glass plate. By tilting the slide it is not difficult to induce the bubbles to coalesce to a single circular bubble. The diameter of this is then measured with a travelling microscope, the figure giving, in conjunction with the thickness of the space, the volume of gas. The solution can then be washed off the slide and glass plate, to be analysed in order to determine the amount of the sample, if this is not already known.

The effect of surface tension on the pressure within the bubble is difficult to correct for under practical conditions, but is not significant when an accuracy of the order of 2 or 3 per cent is aimed at.

Arginine and Deoxyribonucleic Acid Content of Erythrocyte Nuclei and Sperms of some Species of Fishes

THE importance of arginine as a component of the chromatin in nuclei has been known for a long time. This amino-acid has even been considered as a possible 'bond' between the deoxyribonucleic acid (DNA) and the protein because it is so characteristic of all nucleoproteins. If it is so, there should be a relationship between individual amounts of the acid and of arginine in nuclei—provided that nuclei contain no arginine additional to that linked to deoxyribonucleic acid. We have therefore studied the individual amounts of arginine in some nuclei and sperms, compared with the nucleic acid content in the same material.

Material and methods. We worked with seven species of fishes; we used erythrocytes of tench, pike, roach and perch, in which the amount of deoxyribonucleic acid per nucleus is common to a number of fish, and trout, carp and barbel, in which this value is markedly higher[1]. For comparison we used the erythrocyte nucleus of a bird (domestic fowl) and the thymus nucleus of a mammal (calf). We assume that the amount of arginine found in the whole erythrocyte nucleus is approximately the same as that in the chromatin itself; these nuclei are very small and dense, and the quantity of arginine which could be present in the nuclear sap would be negligible.

Erythrocyte nuclei were isolated by a technique described previously[2]. As regards sperms, the measurements were made on whole mature sperms. Cytochemical observations showed that the arginine is chiefly localized in the sperm head; if there is arginine in the intermediate part, the error would not be important. Arginine was estimated by the colorimetric technique of C. Dumazert and R. Poggi[3].

From the results reported in the accompanying table, we see that the ratio of deoxyribonucleic acid content of all the erythrocyte nuclei studied and of some of the fish sperms to the arginine content in

INDIVIDUAL AMOUNTS OF ARGININE AND DEOXYRIBONUCLEIC ACID (IN 10^{-9} γ) OF ERYTHROCYTE NUCLEI AND FISH SPERMS

Species	Erythrocytes DNA	Erythrocytes Arginine	Erythrocytes DNA/Arginine	Sperms DNA	Sperms Arginine	Sperms DNA/Arginine
Perch	2·0	0·37	5·4			
Barbel	3·4	0·64	5·3			
Roach	1·9	0·36	5·3			
Tench	1·7	0·34	5·0	0·85	0·18	4·77
Carp	3·2	0·60	5·3	1·60	0·35	4·40
Trout	4·9	0·96	5·1	2·45	1·50	1·63
Pike	1·7	0·34	5·0	0·85	0·53	1·60
Fowl	2·2	0·45	4·9			
Bull	Calf thymus 6·4	1·49	4·3	3·20	2·16	1·48

the same nuclei is practically constant, in spite of important variations of content of deoxyribonucleic acid. For fowl erythrocytes and calf thymus nuclei the ratio was of the same order of magnitude. In tench and carp, the amount of arginine in a single sperm is about half that in an erythrocyte nucleus. These results are consistent with the hypothesis that arginine molecules are fixed to acidic groups of deoxyribonucleic acid as bonds between the acid and the protein moiety of the nucleoprotein[4]. In trout and pike sperm, however, this correlation does not exist; we suggest, therefore, that in these species the protein moiety itself undergoes a transformation during spermatogenesis, accompanied by a marked synthesis of arginine. In tench and carp, on the contrary, the transformation of the protein residue may be accompanied by the synthesis of a different amino-acid—histidine or lysine—so that the parallel diminution of the arginine linked to deoxyribonucleic acid and of the acid itself would appear directly in the results of our analysis. Finally, the bull sperm shows a deoxyribonucleic acid/arginine ratio which is not very different from that of trout and pike; hence the still unknown nucleoprotein, which might be obtained from bull sperm, if an appropriate method of extraction was available[5], would be a nucleoprotamine rich in arginine.

Variations in the Content of Deoxyribonucleic Acid in the Human Uterine and Vaginal Receptors during the Menstrual Cycle

THE histophotometric method, as used by L. Lison[1], permits the estimation of the deoxyribonucleic acid content of individual nuclei, in sections or smears stained with the Feulgen method. The method postulates that the intensity of the Feulgen stain is directly proportional to the amount of deoxyribonucleic acid present. This very important point has been fully discussed by several authors[2-4], and is now generally regarded as satisfactorily proved.

Applying this optical method, we have studied the variations of the deoxyribonucleic acid content in the nuclei of the endometrial stroma and in the vaginal cells, during several oestrous cycles.

Endometrial stroma. Our measurements, made by the histophotometric method, on individual stroma nuclei, are represented graphically in Fig. 1. The graph has been constructed from numerical results obtained at different times during the oestrous cycle of the same woman and submitted to statistical analysis. Results obtained with other women, under the same conditions, gave similar results. A peak in relative deoxyribonucleic acid content occurs in the proliferative phase between the eleventh and the fifteenth day of the cycle, and is followed by a progressive decrease until the end of the secretory phase. A second peak appears between the twenty-first and twenty-fourth days; it is possible that this apparent increase has no real significance from a statistical point of view, since the confidence limits between the values at the eighteenth and the twenty-first days overlap. Nevertheless, similar findings, made on vaginal smears, lead us to think that the apparent increase shown in the graph is real.

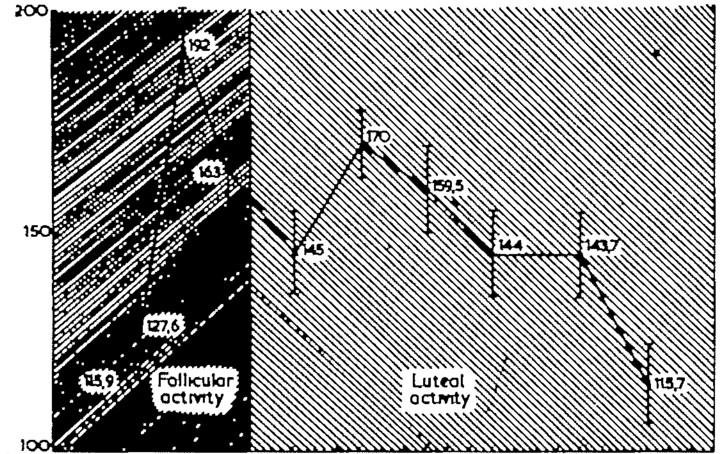

Fig. 1. Diagram of means and intervals of confidence

We conclude from our results that the mean deoxyribonucleic acid content of individual nuclei is not constant but varies, showing a maximum at the proliferative phase and a minimum at the end of the cycle. We can therefore not corroborate the results of Stern and Stuermer[4], obtained by purely chemical methods, who concluded that there is an increase of deoxyribonucleic acid at the late secretory phase.

Vaginal smears. The amount of nuclear deoxyribonucleic acid in vaginal cells has been measured in smears, using the same method, obtained from young mature women. Fig. 2 shows one such set of results, based on measurements made on one woman. An important increase in the mean deoxyribonucleic acid content occurs at the proliferative

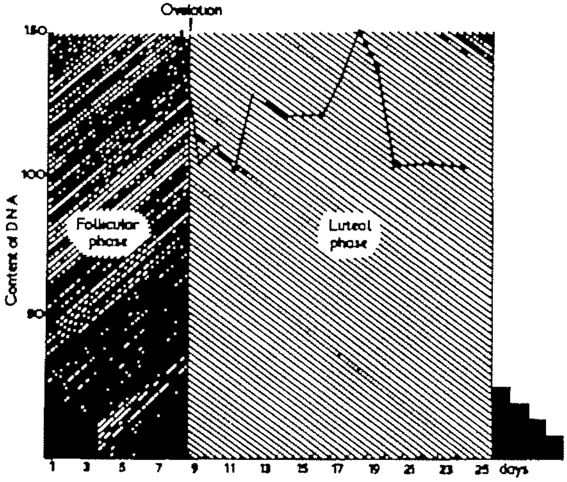

Fig. 2. Variations in the contents of deoxyribonucleic acid in the vaginal cells during a woman's menstrual cycle

phase, with an abrupt post-ovulatory decrease. During the luteal phase, a second peak is shown, at the nineteenth day, followed by a steep decrease, at the premenstrual phase.

Furthermore, we were able to establish that, at any period of the cycle, the amount of deoxyribonucleic acid in pycnotic nuclei is less than that in non-pycnotic nuclei. Pycnosis is accompanied by loss of deoxyribonucleic acid. Therefore the peak at the follicular phase is still more significant, since at this period the karyopycnotic index reaches its highest values. The increase of deoxyribonucleic acid at the peak of the follicular phase must actually be even higher than that shown in the graph.

Finally, it can be stated that the variation of deoxyribonucleic acid in vaginal cells is roughly parallel to the excretion of urinary œstrogen.

In pathological hormonal conditions, similar results were observed in stroma nuclei, sections and vaginal cells in smears: namely, increase in the mean amount of deoxyribonucleic acid accompanying high follicular stimulation (hyperplasia glandulo-cystica), low deoxyribonucleic acid content in hypofolliculinic conditions (endometrial atrophy, senility).

The results of our measurements are not in accordance with the statement of several recent authors, that the nuclear content in deoxyribonucleic acid is constant in all the nuclei of the same organism. As shown by Lison and Pasteels[3] for other tissues, it presents marked fluctuations probably related to the metabolic activity of the cell.

Formation of Glucosides from Phenols in Locusts

During investigations in this laboratory on the fate of foreign organic compounds in locusts, we wished to find out whether these insects formed conjugated glucuronic acids. In the higher animals, glucuronic acid conjugation appears to be a major detoxication mechanism particularly for hydroxy compounds[1]; but there appears to be no record in the literature of this mechanism occurring in invertebrates.

Locusts (*Locusta migratoria*) were therefore fed or injected with various phenols and their excreta were examined by paper chromatography for the corresponding β-glucuronides. *m*-Aminophenol and 7- and 8-hydroxyquinolines were used as test substances, since they were found to be of low toxicity to locusts and their glucuronides were readily detected on paper chromatograms[1,2]. On chromatographic examination of extracts of locust excreta, it was soon discovered that the above phenols were present in combined forms which were not glucuronides. The metabolism of *m*-aminophenol in the locust was therefore studied in greater detail, and it appears that the combined form of this phenol excreted by locusts is, at least in part, β-*m*-aminophenyl-D-glucoside. The evidence for this suggestion was obtained as follows.

Locust fæces collected for two days after the administration of *m*-aminophenol (1 mgm./locust) were extracted with aqueous ethanol and the extract chromatographed on paper on a large scale in *n*-butanol/acetic acid/water (4 : 1 : 5). The appropriate zone was eluted with water and re-chromatographed in *n*-butanol/benzene/ammonia (s.g. 0·88) (5 : 2 : 2). The zone containing the conjugated *m*-aminophenol was again eluted with water. The eluate gave a positive diazo test for aromatic amino groups and had an ultra-violet absorption maximum at the same wave-length as β-*m*-aminophenylglucuronide (that is, 266 mμ in 0·1 *N* hydrochloric acid and 282 mμ in 0·1 *N* sodium hydroxide). However, the eluate gave a negative naphthoresorcinol test for glucuronic acid, and the compound present was shown to have no acid function by paper ionophoresis in buffers at different *p*H's. The conjugate was decomposed more rapidly than β-*m*-aminophenylglucuronide by dilute acid, 30 min. at 100° in 0·5 *N* hydrochloric acid being sufficient for complete hydrolysis, and *m*-aminophenol was readily detected spectroscopically in the hydrolysate. After chromatography of the hydrolysate in *n*-butanol/acetic acid/water (4 : 1 : 5), only *m*-aminophenol and glucose, with traces of xylose, could be found. A small amount of needle-shaped osazone was also obtained from the hydrolysate.

These results suggested that the combined form of *m*-aminophenol in locust fæces was *m*-aminophenylglucoside. An authentic solution of β-*m*-aminophenylglucoside was therefore prepared[5] by deacetylation of the tetra-acetate (m.p. 153–54° and $[\alpha]_D^{20}$ − 31°). The metabolite in locust fæces had the same R_F value as the authentic glucoside in three different solvents, namely, 0·43 in *n*-butanol/acetic acid/water (4 : 1 : 5), 0·17 in *n*-butanol/benzene/ammonia (s.g. 0·88) (5 : 2 : 2) and 0·80 in pyridine/ethyl acetate/water (1 : 2 : 2). The metabolite was also hydrolysed by emulsin, yielding, as shown by paper chromatography, *m*-aminophenol and glucose, thus suggesting for it a β-glucoside structure. This was supported by the negative optical rotation of the concentrated eluates of the metabolite. Thus, short of actual isolation of the metabolite in crystalline form, the above evidence suggests that *m*-aminophenol is partly converted in locusts not to β-*m*-aminophenyl-D-glucuronide, but to β-*m*-aminophenyl-D-glucoside.

This is the first time that a glucoside has been detected as a metabolite of a phenol in the animal kingdom. The formation of β-glycosides (β-glucosides and β-gentiobiosides) from foreign compounds, however, has been shown to occur in the plant kingdom[4], and it has been suggested that it represents a detoxication mechanism in the plant analogous to glucuronide formation in animals.

It is possible that glucoside formation in the locust may be related to the anatomy of its excretory organs, because the Malpighian tubules, unlike the vertebrate kidney, empty into the gut of the insect. The locust has been shown to possess a rich source of β-glucuronidase in its crop[3] and, if β-glucuronides were formed, they might be hydrolysed again in the gut. β-Glucuronide formation on these grounds could be ineffective as a detoxication mechanism. However, it is not known whether β-glucosidase occurs in the locust.

We are grateful to Prof. R. T. Williams for his interest in this work and to the Anti-Locust Research

Centre (British Museum (Natural History)) for grants and supplies of locusts.

Changes in the Vascular and Lipoid Pattern of the Adrenal Cortex of the Rat following Hypophysectomy

As a preliminary to an investigation of the effect of adrenocorticotropic hormone upon the circulation through the adrenal of the rat, it was necessary to study the normal adrenal vascular pattern and, in addition, that of the hypophysectomized rat, at weekly intervals after operation (1–16 weeks). The rats were injected intravitally with a mixture of equal parts of indian ink and distilled water pumped direct into the left ventricle at a constant injection pressure of 160 mm. mercury. The adrenals were fixed in 10 per cent formol saline after ligation of the vascular pedicle, and sections were cut at 50 µ after gelatine or celloidin embedding. Satisfactory preparations were obtained for a study of both the vascular pattern and the lipid distribution.

In normal rats the capillary pattern in the adrenal cortex as demonstrated by intravital indian ink injections shows three concentric zones. (1) An outer injected zone comprising the capillaries of the zona glomerulosa; (2) an intermediate 'zona lucida'[1] of poorly filled capillaries corresponding to the lipid-free cells of the 'zona intermedia'[2] ('transitional zone'[3], 'sudanophobic zone'[4], 'zone of compression'[5]), plus a small but variable depth of the outer part of the zona fasciculata; (3) an inner heavily injected zone of capillaries in the rest of the zona fasciculata and the whole of the zona reticularis. Careful measurements show that the outer edge of the zona lucida corresponds to the inner edge of the zona glomerulosa.

In hypophysectomized rats, owing to cellular shrinkage, which is most marked in the zonæ fasciculata and reticularis, there is a reduction in the inter-capillary distance with a resulting increase in the number of capillaries per unit area. These capillaries are also narrower than in the normal rat. For the first three weeks after operation a normal type of vascular zoning persists; thus with an increase in the depth of the zona intermedia there is a corresponding increase in the depth of the zona lucida (in ink preparations), and the sudanophobe zone (in lipoid preparations). An increase in depth of the zona glomerulosa is a recognized sequel after hypophysectomy[6], but it was found that this increase was maximal at about the fifth week, after which a decrease was observed[1]. Between the fifth and eighth week there is a general reduction in the number and size of the capillaries throughout the cortex, which becomes much less vascular. By this time the zonæ fasciculata and reticularis are very narrow, and there is a tendency towards homogeneity of cell-size throughout the cortex.

The lipid changes in the adrenal cortex of the rat during the first three weeks following hypophysectomy are well known. The striking change is the gradual widening of the fat-free zona intermedia or sudanophobe zone. We have noticed three additional points. (1) The outer half of the zona glomerulosa sometimes becomes free from lipid while the inner half is still heavily laden. To date we have not been able to correlate this change with any specific treatment such as castration or injection of adrenocorticotropic hormone. We have observed differences in the capillary pattern of the inner and outer layers of the zona glomerulosa. It is possible that the zona glomerulosa might consist of two layers with different functions. (2) In rats hypophysectomized 16 weeks previously, the lipid-containing zonæ fasciculata and reticularis are very narrow or completely absent. Either these zones have disappeared or their cells have become completely depleted of lipid. The cortex of these rats is even more poorly vascularized than at 8 weeks. (3) From 5 weeks onwards after hypophysectomy, a few cords or lipid-containing cells from the zona glomerulosa are sometimes found invading the sudanophobe zone.

Conclusion. The poor filling of the capillaries in the zona intermedia of normal adrenals and in adrenals from recently hypophysectomized rats is a surprising finding. Large cells distended with lipid would be expected to press upon capillaries, but the capillary constriction is present at the site of small cells without lipid content. The cells of the zona intermedia still appear smaller than the cells of the adjacent zones in sections of freeze-dried vacuum-embedded adrenals. It is therefore unlikely that the cells of this zone have been artificially reduced in relative size by the ordinary methods of fixation. The Gomori method for alkaline phosphatase on these freeze-dried adrenals gives an excellent picture of the vessel walls and confirms the vascular pattern shown by intravital injection of indian ink.

The true function of the cells of the zona intermedia remains unsolved. There is no evidence for the widely held view that this is the zone of active mitosis in the adrenal cortex[6,7]. If there is a vascular stop-cock mechanism present in this zone, it would not appear to depend upon the mechanical properties of the cells. There remains the possibility of local capillary constriction. Lever has recently described nerve endings in the zona glomerulosa[8].

A more detailed report on the vascular and morphological findings has been prepared by one of us[1]. We are grateful to the Nuffield Foundation for generous support of this work.

Effect of Molybdenum Deficiency on Nitrate Reductase in Cell-free Extracts of *Neurospora* and *Aspergillus*

ALTHOUGH numerous investigators have shown that molybdenum is important for the utilization of nitrate nitrogen by fungi and higher plants[1,2], the role of the micronutrient element in the enzyme systems involved has not been determined. We have recently been able to show that the concentrations of nitrate reductase in cell-free extracts of molybdenum-deficient *Neurospora* and *Aspergillus* are markedly decreased to the extent of one-fifth to one-thirtieth of that of normal tissue. However, the nitrite activity, designated as nitrite reductase[3], of these extracts was significantly increased in *Neurospora* (5297*a*) and *Aspergillus* compared to that of the controls.

Neurospora crassa wild types 146 (microconidial type) and 5297*a* (macroconidial type) were grown on a modified Fries medium containing nitrate as the sole source of nitrogen, and on another in which ammonium nitrate and ammonium tartrate were supplied[2]. *Aspergillus niger* (*M* strain) was grown on a nitrate medium[4]. The removal of molybdenum was achieved by the copper and lead coprecipitation methods as previously described[2,4]; molybdenum was then added back to some of the media which served as the controls. Cell-free extracts and dry-weight measurements were obtained by a method described elsewhere[5]. Protein content of the enzyme extracts was determined by the biuret procedure[6]. The activities of the nitrate and nitrite reductases were measured by the appearance and disappearance, respectively, of nitrite and are expressed in the same units as defined earlier[5]. At least 80 per cent of these enzymes were present in the cell-free extracts as compared to the whole homogenates.

The accompanying table shows that the specific activity of nitrate reductase in cell-free extracts of molybdenum-deficient *Neurospora* is reduced to 10–50 per cent of that of the controls whether grown on a medium containing only nitrate or both nitrate and ammonia as the source of nitrogen. *Aspergillus* showed the same general response (see table) as *Neurospora*; the molybdenum deficiency obtained with *Aspergillus* was more severe as indicated by growth, and accordingly the decrease in nitrate reductase was greater, resulting in values 4–6 per cent of that of the controls. On the other hand, the specific activity of nitrite reductase in *Neurospora* (5297*a*) and *Aspergillus* was considerably increased in cell-free extracts of molybdenum-deficient tissues; in some instances a 15-fold increase was recorded. Preliminary experiments have indicated that the nitrate reductase in *Aspergillus* has the same requirements in terms of its specificity for reduced triphosphopyridine nucleotide and its activation by flavin adenine dinucleotide or flavin mononucleotide as in *Neurospora*. The nitrite reductase appears to be similar to that found in *Neurospora*.

The addition of molybdenum (10^{-3} microgram per 0·5 ml. reaction mixture) to the molybdenum-deficient extracts failed to increase nitrate reductase activity. The mixing of extracts of molybdenum-deficient and normal mycelia of *Neurospora* demonstrated the absence of an inhibitor or activator in the tissues in regard to both nitrate and nitrite reductase activities.

EFFECT OF MOLYBDENUM DEFICIENCY ON NITRATE REDUCTASE OF *Neurospora* AND *Aspergillus* EXTRACTS

Units of nitrate reductase expressed as $\mu M \times 10^{3}$ of nitrate formed per mgm. protein

Fungus	Nitrogen source	Treatment	Per cent growth	Nitrate* reductase
Neurospora crassa No. 146	Nitrate only	+ Mo	100	20·5
		− Mo	29	4·8
5297*a*	Nitrate only	+ Mo	100	10·7
		− Mo	32	1·2
146	Nitrate and ammonia	+ Mo	100	48
		− Mo	50	20
5297*a*	Nitrate and ammonia	+ Mo	100	14·2
		− Mo	55	2·2
Aspergillus niger *M* strain	Nitrate only	+ Mo	100	45·3
		− Mo	5	1·6
M strain†	Nitrate only	+ Mo	100	38·8
		− Mo	31	2·4

* Reaction mixture contained the following: 0·1 ml. 0·1 *M* potassium nitrate, 0·02 ml. 10^{-3} *M* potassium cyanide, 0·04 ml. flavin mononucleotide (500 μgm./ml.), 0·04 ml. reduced triphosphopyridine nucleotide (2 μM/ml.). The reaction mixtures were made up to 0·5 ml. with 0·1 *M* pyrophosphate buffer, *p*H 7·0.

'+ Mo' cultures contain 2 μgm. Mo per 125 ml. (*Neurospora*) and 2 μgm. Mo per 50 ml. (*Aspergillus*).

† In this experiment, 10^{-3} μgm. Mo only was supplied to the "− Mo" flasks.

It has already been shown that individual deficiencies of iron, zinc and manganese in *Neurospora crassa* (5297*a*) resulted in a marked increase in nitrate reductase, while a nitrogen deficiency caused a striking decrease[3]. We have recently produced a copper deficiency in *Neurospora* (5297*a* and 146) by a double sulphide precipitation technique at *p*H 3·7 [2,4], which resulted in a four-fold increase in specific activity of nitrate reductase as compared with normal tissues. Thus only a nitrogen deficiency (which presumably affects protein metabolism) and molybdenum deficiency lower the nitrate reductase. Whether molybdenum is a component of the nitrate reductase system or whether it exerts its effect indirectly by influencing protein metabolism is not known. Experiments now in progress may elucidate this point.

This investigation was supported in part by research grants from the National Institutes of Health, United States Public Health Service, and the Office of Naval Research.

Note added in proof. Since this communication was submitted we have demonstrated that both the molybdenum content and specific activity of nitrate reductase increase with purification of the enzyme. Moreover, inactivation of the enzyme by dialysis against cyanide is accompanied by a decrease in molybdenum content of nitrate reductase. The inactivated enzyme is almost fully restored by the addition of molybdenum trioxide or sodium molybdate as compared to the other micronutrients.

The Röntgen: Deficiencies in Present-day Free-Air Chamber Standards

The röntgen is defined as "that quantity of X- or gamma-radiation such that the associated corpuscular emission per 0·001293 gm. of air produces, in air, ions carrying 1 e.s.u. of charge of either sign". An ionization chamber designed for the realization of this unit must therefore provide sufficient space around the air volume in which the primary ionization occurs to permit the corpuscles from it full range, effectively. In the parallel-plate type of chamber, this involves not only sufficient electrode spacing, but also adequate dimensions at right angles, that is, lateral to the X-ray beam. It was recognized in the design of the typical standards set up more than twenty years ago in Great Britain[1] and the United States[2] that the actual electrode spacing need not be so great as might at first sight be thought necessary on theoretical grounds. Thus for 200-kV. X-rays, a plate spacing approaching 70 cm. (with effectively equal lateral dimensions) is theoretically desirable, whereas, in fact, the ionization losses with dimensions considerably less than these may be negligible. Thus 10 cm. only was adopted as the plate-spacing in the chamber set up at the National Physical Laboratory, Teddington, and 12 cm. in that at the U.S. Bureau of Standards.

We have shown in our experiments that, assuming the chamber geometry to be adequate in other respects, these values of plate-spacing would lead to ionization losses of about 0·5 and 0·1 per cent respectively with 200-kV. medium-filtered radiation. However, critical consideration of the lateral geometry in these two chambers (including electrolytic tank studies to elicit the electrostatic field conditions) reveals the existence of relatively serious deficiencies. Thus the effective lateral dimension of the collecting region in the National Physical Laboratory chamber was found to be a little less than 7 cm., largely as a result of the incorporation of unnecessary and, indeed, undesirable lateral guard plates. The corresponding dimension in the U.S. National Bureau of Standards chamber was estimated to be 8 cm. The resulting lateral losses in both chambers are hence far more serious, and we have concluded that they exceed 2 per cent in the National Physical Laboratory chamber and are almost 1·5 per cent in the National Bureau of Standards chamber at 200-kV.

These deductions were made from a series of experiments, employing a free-air chamber pair in conjunction with a Kemp-type precision X-ray comparator[3], one of the chambers being housed in a pressure-casing so that the effective dimensions of the electrode assembly could be varied by alteration of the air pressure within the chamber. As a check on our conclusions in the case of the National Physical Laboratory chamber, we built an exact geometrical replica of the latter and made a direct comparison of it with our own over a range of X-ray qualities (again using the X-ray comparator). The losses predicted by the pressure-change experiments and those observed by direct comparison are set out in the accompanying table.

kV.	Filter	Losses of N.P.L. chamber due to inadequate geometry	
		From pressure-change experiments	By direct comparison
60	Nil	Nil	Nil
75	1 mm. Al	Nil	Nil
100	1 mm. Al	0·4 per cent	0·4 per cent
145	0·2 mm. Cu + 1 mm. Al	1·9 ,,	2 3 ,,
190	0·47 mm. Cu + 1 mm. Al	2·5 ,,	2 9 ,,

Thus the existence of the losses was confirmed by the direct comparison, which indicated that if anything the losses had been under-estimated in the original series of experiments.

This investigation is being described in a paper before the International Congress of Radiology at Copenhagen during July; an account of the experiments themselves will be published elsewhere in due course.

Alternating-Current Energy Losses in Iron Laminations at Magnetic Saturation

A limit to the power output of most rotating electrical machines is set by magnetic saturation in the teeth of the punchings employed. Designers of these machines have, however, never had data available on the specific iron losses of the materials they use for alternating flux densities higher than about 75 per cent of the saturation value. The usual methods of measurement, applied to specimens of the material, fail completely at higher flux densities than this because the power factor becomes very small and the magnetizing current very high. The former introduces difficulties when wattmeters are used, and the latter when thermal methods are contemplated. We have successfully used the following method.

A small four-limbed core of laminations was built up, the specimen under test being a single strip near the centre of one limb. This limb was wound with a magnetizing coil and was of smaller cross-section than the other three. Strips, of the same width as the test piece, of a non-ferromagnetic resistance material were placed above and below the test piece and separated from it by small air spaces. A pair of thermocouple junctions in opposition were placed, one on the test piece and the other on the adjacent surface of a resistance guard strip. This thermocouple circuit was connected to a very sensitive and stable photo-electric galvanometer amplifier which was used only as a null detector. In carrying out a test, the specimen was magnetized from a 50 c./s. supply. At the same time the guard strips were heated by passing a current through them, this being adjusted by trial to give the same rate of rise of temperature. Thus, for a given flux density B_{max} in the specimen and correct adjustment of the current in the guard strip, simultaneous closing of both circuits would produce no deflexion of the galvanometer. Then, from the specific heats of the two materials and the electrical resistivity of the guard strip, the iron loss in the specimen could be determined. Alternatively, and as a check, a method of direct calibration was also used in which the specimen was first heated by the iron losses and then, secondly, heated by passing a current through it also.

The method has worked well and has a number of advantages. The magnetizing current need not be applied for a period greater than about four seconds for each reading. There is therefore no difficulty due

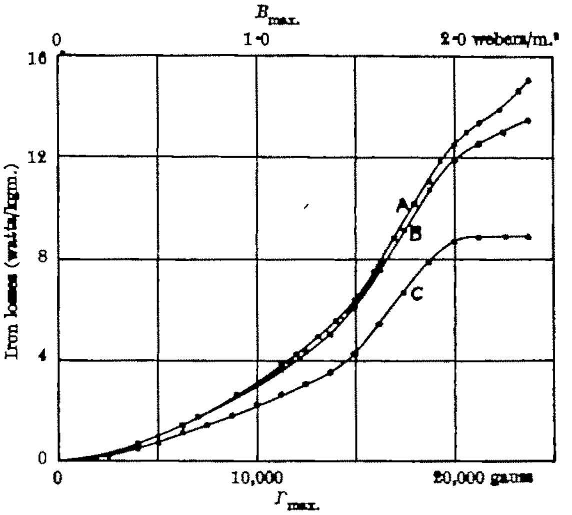

Fig. 1

to heating up of the magnetizing coil, which can be heavily over-run in order to reach high flux-densities. Since the basis of the method is that specimen and guard strips shall have the same rate of rise of temperature, there is no difference in temperature between them and so no errors due to flow of heat from one to the other.

It is advisable that any results presented should correspond to a sinusoidal flux density. It seems to be almost an experimental impossibility to maintain a sinusoidal flux wave-form at these very high flux densities with equipment of reasonable size, although Cormack[1] has described an elaborate system which he used up to fairly high flux densities. In the present work, no great precautions were taken to secure a good wave-form; but form-factors of the induced e.m.f. waves were determined and a correction applied for the resulting increased calculable eddy-current component of the total iron loss.

Tests have been made on several materials. The results for a sample of ordinary dynamo iron, containing about 0·5 per cent silicon, are of most practical interest. These are shown in the graphs. The highest flux density reached was $B_{max} = 23{,}750$ gauss (2·375 webers/m.²) with an applied field $H_{max} = 2{,}500$ oersted. The curves shown are: (*A*), observed total iron loss; (*B*), total iron loss corrected to sinusoidal flux density; (*C*), hysteresis component of total loss, obtained by subtracting the calculated eddy-current component. The curves indicate that the hysteresis component reaches a saturation value. If this is indeed the case, the iron losses at flux densities still greater than the highest figure mentioned above, should these be required, are obtainable by adding a calculable eddy-current component to the saturation hysteresis loss.

A Presumed Ascomycete from the Upper Carboniferous

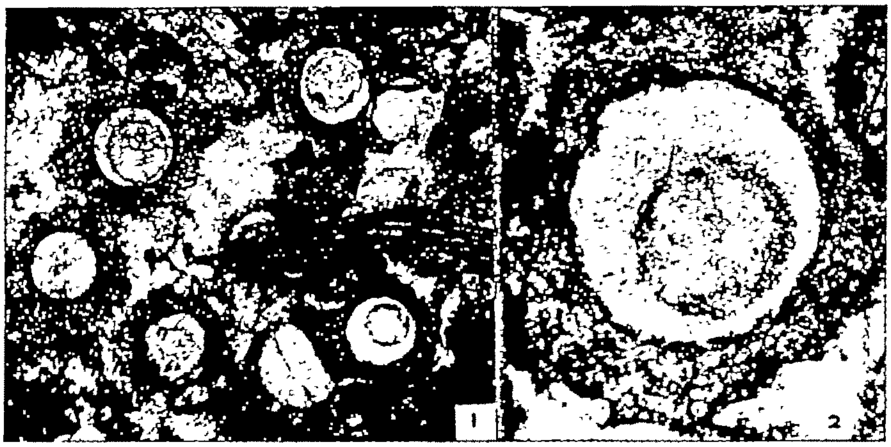
THIS fungus was found during a recent examination of a single section cut from a coal ball collected at the Moorside Colliery, near Halifax, Yorkshire. The section has been in the departmental teaching collection at Glasgow for many years; but it has rarely been examined as it does not contain interesting specimens of other plants.

The material consists of sections of seventeen spherical fructifications 275–400 µ in diameter with single central cavities 125–250 µ in diameter. The wall structure is similar to that of an ascocarp, being made up of four to eight layers of thick-walled closely packed hyphæ 5–20 µ in diameter. In most places the hyphæ are cut in transverse section and they are too closely interwoven to permit detailed study of their structure; but in the few areas where they run obliquely they can be seen to be septate and branched. There is no sign of an ostiole. The fructifications lie freely, in some cases in contact with each other.

A ring of dark material can be made out in a number of the cavities. The details of the structure of this ring cannot be distinguished; but in its position and dimensions it closely resembles the layer of ascogenous cells around the cavity of the young perithecium of some of the Sphæriales. Such traces of cellular arrangement as can be made out do not conflict with this similarity.

After completing the examination of the above material, similar fructifications were discovered in sections of a coal ball taken from the Bouxharmont seam at the Werister Colliery, Liège. Prof. Suzanne Leclercq courteously made the coal ball available for this laboratory, and a series of sections are now being prepared from it. The sections so far examined have confirmed the rounded shape of the fructifications, the nature of the cell walls and the absence of an ostiole. In some cases a small number of irregularly arranged rounded bodies have been seen in the cavities. They are 30–50 µ in diameter and have a slightly thickened wall.

Definite evidence of asci or ascospores has not been found in any section, but great resemblance to living ascomycetes is shown by the shape, the structure of the wall and the general appearance of the contents of the cavity. There have been many



(1) Group of fructifications from Moorside Colliery. (2) Single fructification, showing ring of dark material in the perithecium cavity

reports of casts and impressions of perithecium-like structures from Tertiary rocks, but there are no previous records of a section of a fungus of this type from the Palæozoic.

It is thought that the fructifications are of a new species of ascomycete, and a detailed account and diagnosis will be published elsewhere.

Secondary Growth in Petioles and the Partial-Shoot Theory of the Leaf

Isolated leaves are able to live independently in soil with root systems of their own induced from their petioles by the application of synthetic hormones[1]. Leaves of *Amaranthus gangeticus*, Linn. var. *tristis* were grown in soil with such root systems induced by an aqueous solution of β-indolyl butyric acid of the strength of five parts per million. After a month the petioles became thicker and stouter, and transverse sections, a photomicrograph of one of which is given in Fig. 1, revealed an anomalous type of secondary growth peculiar to the stem of the species.

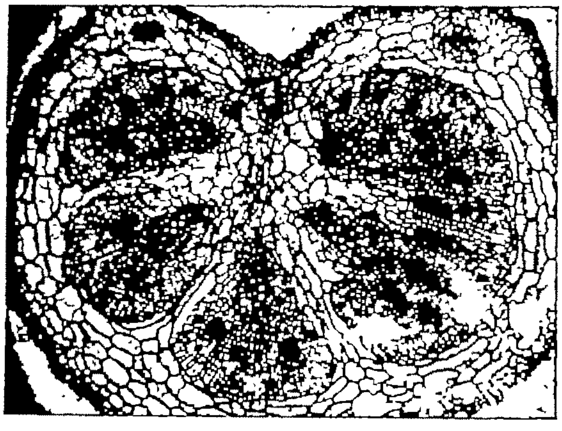

Fig 1. Transverse section of the petiole of a rooted leaf of *Amaranthus gangeticus*, Linn. var *tristis*, showing an advanced stage of secondary growth

Fig. 2 depicts a transverse section of a petiole of a leaf of the same age attached to the plant and shows no secondary growth. Secondary growth is initiated outside the original vascular bundles by accessory cambium formed in distinct arcs. Small discrete groups of secondary xylem are cut off inwards and are embedded in parenchymatous conjunctive tissue whereas phloem is poorly developed. No interfascicular cambium is formed and secondary growth takes place within the primary bundles by the activation of the rudimentary fascicular cambium.

Secondary growth is also seen in the petioles of rooted leaves of *Chenopodium album*, Linn. and *Ipomœa batatas*, Lamk., and the types are the same as seen in their respective stems. It is known that auxin controls cambial growth[2]. In these cases it seems that the formation of accessory cambium and the activation of fascicular cambium are due to the synthetic hormone, which is also responsible for the root formation.

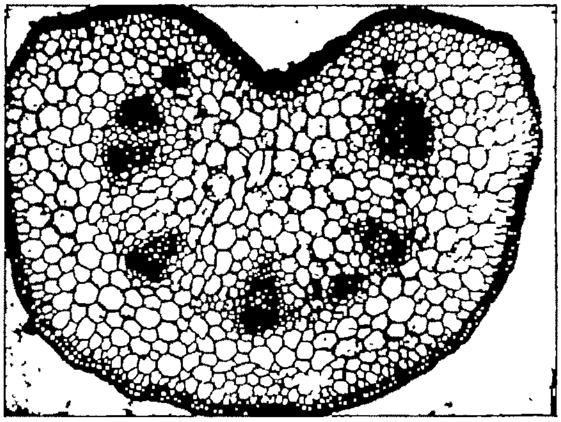

Fig. 2. Transverse section of the petiole of a rooted leaf of *Amaranthus gangeticus*, Linn. var. *tristis* of same age as that of the rooted leaf, but attached to the plant

The phenomenon of the production of secondary growth in petioles has a very important bearing in determining the morphological nature of the leaves. It is seen that the type of secondary growth in the petiole is the same as in the stem of a particular species and, in our opinion, this fact is one of the strongest pieces of evidence in support of the partial shoot theory of the leaf as elaborated by Arber[3].

Protective Effect of Aged Vaccines on a Neurotropic Virus Infection in Mice

A NUMBER of clinical observations have established that recent immunization with diphtheria or whooping cough vaccines renders children more susceptible to poliomyelitis infection (see Hill and Knowelden[1] for references). A similar effect has been demonstrated in mice infected with the virus of mouse encephalomyelitis (*GDVII* strain) in experiments which are being reported fully elsewhere. During the course of the work, however, it was observed that the injection of vaccines which had been stored for several months no longer made the mice more susceptible to virus infection, but instead exerted a protective effect. It is felt that these findings, if confirmed, might have an important bearing on both clinical and biological problems.

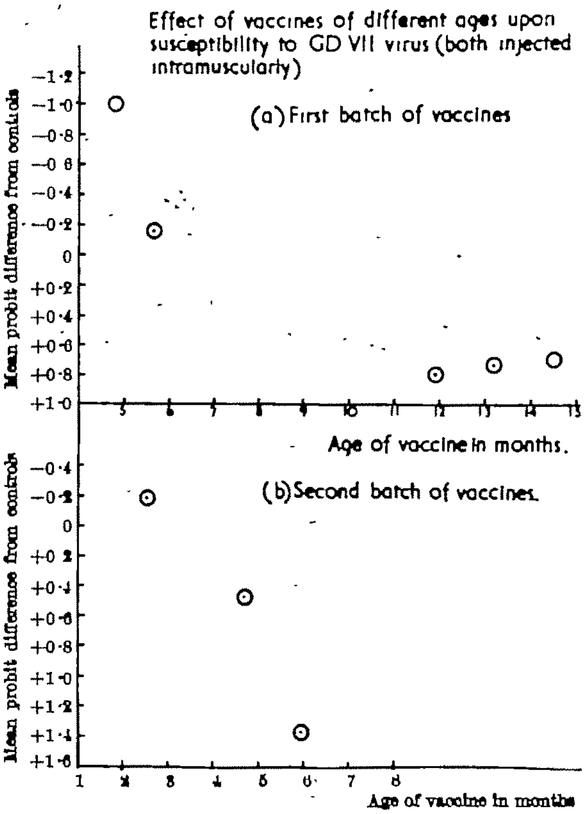
The vaccines used were Diphtheria *A.P.T.*, prepared by Burroughs Wellcome, and a pertussis vaccine prepared by the Medical Research Council. Both were stored at 0–3° C. throughout the experiment. Serial tenfold dilutions of a standard suspension of virus-infected mouse brain (containing 3×10^{6} intracerebral *LD* 50's per ml.) were injected into batches of three- to four-week old mice, 0·03 ml. into the calf muscle of each mouse; and from the numbers in each batch which succumbed, the 50 per cent lethal dilution was estimated by probit methods[2]. In the experimental series, a standard dose containing one part of each vaccine and four parts of distilled water was injected into the same leg muscles, usually 48 hr. after the injection of virus, and the 50 per cent lethal dilution again calculated. The altered susceptibility of the vaccine-treated series could then be expressed in terms of the 'mean probit difference'[2] between the experimental and the control series.

The first supply of vaccines was obtained and tested in February 1951. The diphtheria vaccine had been prepared in October 1950, and was marked as fit for use until October 1952; the date of manufacture of the pertussis vaccine was not known.

When first tested, the combined vaccines increased approximately tenfold the susceptibility of mice to virus given 48 hr. previously. A month later, however, treatment with the same batch of vaccines produced little or no apparent increase in susceptibility. In September, the same vaccines were tested again, and were now found to decrease nearly tenfold the susceptibility of the mice to virus. This protective effect of the vaccine treatment was confirmed in a further experiment in November, and again in December. The probability of the apparent protective effect observed in these three experiments arising as a result of chance variation alone is less than one in a thousand.

A fresh supply of vaccines was obtained in December 1951. The pertussis vaccine was from the same batch as before, while the Diphtheria *A.P.T.* was from a new lot, prepared in October 1951. The fresh vaccines again increased susceptibility when first tested (though to a lesser extent than the first batch), but by February showed a slight protective effect, and, when last tested, in March 1952, increased the resistance of the mice more than tenfold, with again a very high degree of statistical significance ($P < 0{\cdot}001$).

In the accompanying figure are plotted the mean probit differences between the control mice and the groups receiving injections of the combined vaccines 48 hr. after the injection of virus. The initial increase in susceptibility, replaced in the course of a few months by an increase in resistance, is apparent for both batches of vaccine. Since the effect does not appear to be related to the season of the year, one may conclude that the properties of one or both vaccines were altering with age.



Effect of vaccines of different ages upon susceptibility to GD VII virus (both injected intramuscularly)

No explanation of the protective effect of the aged vaccines is offered at this stage.

The expenses of this research were met by a grant from the Nuffield Foundation for virus work in this Department. My thanks are also due to the Medical Research Council for financial support, and to Dr. F. K. Sanders for advice and help.

Agglutination of Red Cells by *Cl. welchii*

THE hæmagglutination of sheep red cells by *Cl. septicum* and the inhibition of the reaction by specific serum has already been described[1].

Strains of *Cl. welchii* types *A*, *B*, *C* and *D*, respectively[2], grown on 5 per cent sheep blood agar for 48 hr., were suspended in normal saline solution and were treated with formalin to inactivate the hæmolysin. When two-fold dilutions were added to washed sheep red cells, incubated at 37° for an hour, and then left overnight at room temperature, a sharp end-point in the agglutination of the red cells was obtained. *Cl. welchii* types *B* and *D* were more active than types *A* and *C* (see table). Washed cultures

EFFECT OF FORMALIZED CULTURES OF *Cl. welchii* ON FRESH SHEEP RED CELLS

Type of *Cl. welchii*	Dilutions of cultures					
	1/16	1/32	1/64	1/128	1/256	1/512
A	+	–	–	–	–	–
B	+	+	+	+	+	–
C	+	–	–	–	–	–
D	+	+	+	+	–	–

+, Agglutination of red cells : –, no agglutination.

from agar showed a higher titre of agglutinins than those from fluid medium : supernatant fluids from broth cultures were almost inert.

As was the case with *Cl. septicum*, the reaction was inhibited by the appropriate immune sera. In order to avoid confusing non-specific agglutination of red cells by these sera, a sheep red cell + horse or rabbit immune serum system was used and gave clear-cut results. Serial two-fold dilutions of antisera were incubated with red cells for half an hour and were then completed with two hæmolytic doses of bacterial culture. Both antibacterial and antitoxic sera inhibited agglutination, but the latter were the more effective. It was possible to distinguish type *A* from types *B*, *C* and *D* in this way, but the overlap between *B*, *C* and *D* prevented any sharp differentiation of these groups.

Treatment of antitoxic and antibacterial sera with heavy suspensions of the corresponding organisms failed to remove group antibodies. The end-points in hæmagglutination were also unaffected when the antisera were added to red cells, previously treated with the homologous strain, in an attempt to remove anti-agglutinins.

These experiments, which confirmed in part those reported by Gurtürk[3], show that the agglutinating factor in *Cl. welchii* cultures is associated with the bacterial cell but not with the toxin. As this factor is neutralized not only by the homologous antibody but also, except in the case of type *A*, by other antisera, the test can be used in identifying *Cl. welchii*, but not for typing the different strains.

Control of a Seed-borne Disease by *Chætomium cochlioides* Pall., under Natural Conditions

MANY workers have reported striking antagonism between plant pathogens and saprophytes. Most of this work has been done in pure culture or in soil partially or completely sterilized before introduction of the test organisms. There are comparatively few records of disease control under natural conditions by the introduction of an antagonistic organism.

The work briefly reported below, based on earlier investigations in the Division of Plant Pathology, University of Minnesota, is an example of such control. It was then shown that when certain Brazilian isolates of *Chætomium cochlioides* Pall. were introduced into unsterile soil, the severe blight caused by *Helminthosporium victoriæ* M. and M. on oat seedlings was prevented. Similar results have now been obtained with a more active strain of *C. cochlioides* using oat seed heavily infected naturally with ***Fusarium nivale*** (Fr.) Ces.

Of several media used to increase inocula of the antagonist, oat-straw saturated with a 2 per cent glucose solution was most satisfactory. This was loosely packed into litre jars, sterilized and incubated for three to four weeks at 20° C. after inoculation. The straw became permeated with the fungus and covered with perithecia and was easily incorporated into soil in this condition.

A medium loam taken from plots under continuous cultivation was used with no treatment other than those given below. Oat seed heavily infested by ***F. nivale*** was obtained from the Norwegian Government Seed Testing Laboratory, Vollebekk, Norway. 4-inch pots were two-thirds filled with soil, and 20 gm. of the oat straw inoculum was spread over the surface on which were placed thirty seeds. These were finally covered with about 3 cm. of soil. The pots were kept in a cool frame at a temperature of 13–16° C.

In the following experiment, typical of a number, the treatments were : (1), (2) and (3) oat-straw cultures of three strains of *C. cochlioides* ; (4) seed treated with an organo-mercurial fungicide ; (5) uninoculated oat-straw. Six replicates were used, and the results obtained after five weeks are shown in the accompanying table.

CONTROL OF SEEDLING BLIGHT OF OATS

Treatment	Strain	Mean percentage emergence	Condition of the plants at 2/3 leaf stage		
			% Dead	% Blighted	% Healthy
1 Oat-straw culture	*A*	87·2	0	0	87·2
2 ,, ,, ,,	*B*	81·7	8·9	20·6	52·2
3 ,, ,, ,,	*C*	31·2	20·6	10·6	0
4 Organo-mercurial fungicide	—	88·3	0	3·9	84·4
5 Uninoculated oat-straw	—	26·1	17·8	8·3	0

The results show quite clearly the excellent control of disease obtained by strain *A* of the antagonist. This was as good as, if not slightly better than, that obtained by the proprietary seed-dressing. The importance of using suitable strains is demonstrated by the failure of strain *C* to produce any control and the intermediate results obtained with strain *B*. Results comparable to the above have been obtained with strain *A* using a variety of inoculation methods.

The mechanism of the control which is obtained has not yet been determined, although a certain amount of evidence has been accumulated which suggests that it is by the production and subsequent diffusion into the outer layers of the infested seed of one or more antibiotic substances. It is interesting to note, however, that the fungus is not strikingly antagonistic to ***F. nivale*** or other pathogens in pure culture. This aspect of the problem is being investigated, as is also the use of strain *A* in the control of other seed-borne and soil-borne pathogens, and together with the above will be reported in greater detail at a later date.

I wish to thank Dr. R. K. S. Wood for valuable help and criticism throughout these investigations.

Eperythrozoon parvum, a Filterable Blood Parasite of Swine

INFORMATION relative to the filterability of species of the genus *Eperythrozoon* apparently has not been published previously[1]. These blood parasites are classified[1] in the order Rickettsiales, a group which includes numerous filterable agents. It is apparent that passage or retention of *Eperythrozoon* by the usual bacteriological filters would not serve as any criterion for altering their present classification.

Foote *et al.*[2] reported that the parasites of swine, *Eperythrozoon suis* Splitter and *Eperythrozoon parvum* Splitter, were both filterable through 12-lb. Mandler and possibly finer filters. This observation was made in connexion with studies on a condition of swine termed by these workers "virus anemia". However, the infectious nature of eperythrozoa was not recognized and these parasites were referred to as "artefacts" or "reactionary bodies".

A study was made of the filterability of *E. suis* and *E. parvum* in swine blood serum. Details of the filtration procedures are given in a report of this work[3]. At negative pressures not exceeding 100 mm. of mercury, *E. parvum* was found capable of traversing the 8-, 12- and 14-lb. Mandler candles. Passage was also effected through the medium (*N*) and fine (*W*) Berkefeld candles, and the Seitz *EK*. The parasite was also recovered on double filtration through two 8-lb. Mandler candles in one instance, and two 12-lb. Mandlers in another. Complete retention was obtained on double filtration with the Seitz *EK*. These filters completely retained *Serratia marcescens* in saline (300 million bacteria per c.c.) adjusted to the approximate pH of swine serum (pH 7·4).

DIFFERENTIATION OF *Eperythrozoon suis* AND *Eperythrozoon parvum*

	E. suis	*E. parvum*
Morphology	Large rings (0·8–1·0 μ) with much chromatin. Discoid forms and very large irregular rings (2–3 μ) may be present	Small rings (0·5–0·8 μ) with numerous coccus forms of considerably smaller size. Often found in large numbers on single erythrocytes when organisms are rare in blood
Pathogenicity	Consistently pathogenic in heavy infections in splenectomized or non-splenectomized pigs. Etiological agent of acute eperythrozoonosis of swine in the field	Relatively non-pathogenic. May produce mild to severe anæmia in some experimental cases. Not known to produce acute eperythrozoonosis in the field
Prepatent period	6·1 days (average of 43 initial attacks)	13·1 days (average of 21 initial attacks)
Patent rise of infection	3·3 days (average of 43 initial attacks)	7·0 days (average of 21 initial attacks)
Incubation period	9·7 days (average of 43 experimental cases)	26·6 days (average of 3 experimental cases)
Susceptibility to Neo-arsphenamine	Highly susceptible to doses of 15 mgm./kgm. or greater	Relatively resistant. Doses of 40–45 mgm./kgm. are effective irregularly
Cross immunity	Pigs pre-mune with *E. suis* are readily infected with *E. parvum*	Pigs pre-mune with *E. parvum* are readily susceptible to acute and fatal infection with *E. suis*
Interference	*E. suis* displaces *E. parvum* when infection is superimposed	*E. parvum* is suppressed in initial mixed infections with *E. suis*
Filterability	Usually retained by the fine diatomaceous earth filters and the Seitz *EK* at negative pressures of 100 mm. mercury	Readily passes the fine diatomaceous earth filters and the Seitz *EK*. Uncomplicated strain may be established by filtration of serum containing the two species

In one instance *E. suis* passed the *N*-Berkefeld, but was retained by the Seitz *EK*. In another experiment, passage was effected through the 8-lb. Mandler, but not the 14-lb. Mandler, the *W*-Berkefeld, or the Seitz *EK*. In an additional trial, the parasite traversed the 8- and 14-lb. Mandlers, but was retained by the *W*-Berkefeld and the Seitz *EK*. *E. suis* was not recovered in nine other filtration experiments from serum or serum filtrates of known carriers or acute experimental cases.

E. parvum was repeatedly separated from *E. suis* and established in a pure, uncomplicated infection by filtering the serum portion of blood known to contain both species. In several experiments involving microscopically negative carriers, eperythrozoa were recovered from the cellular portion of blood only; the unfiltered serum was not infectious. This is regarded as additional evidence of the infectious nature of the *Eperythrozoon* structure, since these blood forms possess a distinct affinity for the erythrocyte.

As a result of these studies, additional information has been compiled relative to the differentiation of *E. suis* from *E. parvum*. This is summarized in the accompanying table.

Reversal of the Heart-beat in Tunicates

THE periodic reversal of the heart-beat in Tunicates has been considered by us[1] on the basis of the back-pressure theory originally propounded by Lahille[2]. Recently, Millar[3] has concluded from experiments on isolated hearts of *Ciona intestinalis* that the back-pressure theory is untenable.

Although we failed to observe reversals in isolated hearts of *Ascidiella aspersa*, we stated that we saw no reason to suppose that they should not occur. We would not, however, expect them to be regular, and in fact the results quoted by Millar give periods ranging from 1½ to 18½ minutes between reversals. These reversals occurred after several hours of one-way beating, a fact which is in agreement with the back-pressure theory, and only when the heart is very abnormal does the reversal effect become apparent.

It is important to realize the scope of the back-pressure theory. As we have pointed out[1], it merely gives a reason for the stopping of the beat in a particular direction. How the opposite beat afterwards takes over is not explainable in terms of the theory, nor in fact is the mechanism by means of which successive beats one way dominate until reversal.

Millar considers that there is a "pattern of reversal inherent in the heart", but admits that periodic pressure changes may, of course, influence the behaviour of the heart in the intact animal. The regularity of the reversals in the intact animal and the experimental fit to the theoretical that we obtained, as opposed to the wide variations in times between reversals in the isolated heart, are very strong evidence that back-pressure is the controlling mechanism in the intact animal to an overriding extent. In other words, there are two stable modes of action of the heart—abvisceral and advisceral—and back-pressure is the mechanism causing the limitation of one mode in the intact animal. How the transition to the other mode takes place is no concern of the theory. It seems almost certainly to be bound up in some way with the capacity of each end of the heart to initiate contractions. In an isolated and therefore abnormal heart, the beats one way might well be expected to fail to dominate the other consistently, especially when the heart is almost moribund.

We have recently repeated Millar's experiments but did not observe reversal in the isolated hearts of four specimens of *Ciona intestinalis* even after ten hours. However, in two specimens, by merely touching the appropriate end of the heart, reversal could be made to take place at will. In one of the cases the beat continued in the reversed direction, whereas in the other case the reversal was only temporary. It is difficult to know to what extent conclusions can be drawn at all from experiments on hearts not *in situ*, but this is certainly in favour of the idea of two stable modes of action. When reversals occur in the isolated heart without direct mechanical stimulus it could well be due to a variety of causes: local variations in temperature, metabolism, progressive fatigue, weakness of the mechanism controlling the dominance of one mode, etc. It is not, however, valid to conclude that the back-pressure theory is untenable. In fact it seems to us that an "inherent pattern of reversal" can have no significance at all unless it be a *regular* pattern in some way. A mere alternation between the two available directions of beat in circumstances which preclude back-pressure phenomena is insufficient evidence to disprove a verified quantitative theory of the regularity of reversal in the intact animal.

We would stress the need not only for a very thorough re-investigation of the peculiar muscle cells of the Tunicate heart but also the need for definite evidence as to whether the heart is myogenic or neurogenic, before any *complete* theory of the reversal phenomena can be formulated.

C. A. Haywood
H. P. Moon

University College, Leicester.
Jan. 6.

Haywood, C. A., and Moon, H. P., *J. Exp. Biol.*, **27**, 14 (1950).
Lahille, "Contributions à l'étude anatomique et taxonomique des Tuniciers" (Toulouse, 1890).
Millar, R. H., *Nature*, **170**, 851 (1952).

In the above communication, Haywood and Moon stress the irregularity of reversal in the isolated hearts in my experiments, and suggest that the reversal of these hearts is due to their abnormal condition, or to random variations in their environment. It seems to me that the fundamental behaviour of these hearts is their repeated reversal and that it is the irregularity which is more likely to be an abnormality.

However, the most important aspect of the whole question has, I think, been adequately dealt with by von Skramlik[1] in a very important paper which was not referred to in Haywood and Moon's (1950) original contribution. Von Skramlik not only followed the repeated reversal of isolated hearts of *Ciona intestinalis* (after an initial period of one-way beating), but also—and this seems very important—he located a controlling centre at each end of the heart, isolated each of these two centres, and found that each had a rhythmically changing pattern of beating (see von Skramlik, p. 622, Abb. 6), in which series of beats and short pauses alternated. After each pause the isolated controlling centre restarted beating slowly before acquiring its full rate. This activity of the controlling centres is precisely the basis of the "pattern of reversal inherent in the heart" to which I referred in my letter to *Nature*. The heart, therefore, it seems to me, possesses its own mechanism for periodically stopping and reversing, however the action of this mechanism is modified by blood pressure in the intact animal.

A number of other points may also be made in connexion with Haywood and Moon's (1950) paper. They state (p. 15) that "A modified form of the back pressure theory has been put forward by von Skramlik (1930) in which reversal is associated with the periodic contraction of the whole animal, bringing about a reduction of the capacity of the blood vessels by constriction, thus facilitating a build-up of back pressure and subsequent reversal". This statement does not give von Skramlik's view of the activity of the ascidian heart, and in the experiments reported by him (1930) there was no question of "periodic contraction of the whole animal". The contractions in question followed stimulation applied by the experimenter. Von Skramlik states that in the normal, relaxed state of the animal it is the rhythmically varying frequency of beating of the two controlling centres that is responsible for reversal.

Enriques (1904), in stating that there is merely an oscillation of blood to and fro in the vessels, was later proved to be wrong by von Skramlik (1929), who demonstrated a true circulation. Indeed, it is difficult to see what fundamental difference there is in the ascidian blood vessels, as opposed to the system of many other animals possessing a true circulation, which necessitates the application of a theory of back-pressure. But this is an aspect that I would not stress as it depends on measurement of the capacity of different parts of the blood system, which to my knowledge has not been made.

I agree that "It is difficult to know to what extent conclusions can be drawn at all from experiments on hearts not *in situ*", yet this technique has given useful experimental results in other animals. I believe that, when isolated hearts, albeit after an interval of one-way beating, behave in essentially the same way as do hearts *in situ*, and furthermore when an adequate functional basis (rhythmic variation in the controlling centres) is revealed, the conclusion is justified that the tunicate heart has its own inherent pattern of reversal.

FORTHCOMING EVENTS

Monday, July 6—Thursday, July 9

Society for Applied Bacteriology (at Oxford).—Summer Conference.

Tuesday, July 7

Symposium on "Antibiotics, their Production and Uses in Industry".

Tuesday, July 7

British Psychological Society, Industrial Section (in Room 105, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 1 p.m.—Mr. Geoffrey Thomas: "An Enquiry into the Mobility of Labour".

Bone and Tooth Society (at the Institute of Orthopaedics, 234 Great Portland Street, London, W.1), at 5 p.m.—Symposium on "Jaw Lesions". (Dr. R. B. Lucas: "Adamantinomas", Dr. O. H. G. Price: "Osteolytic Mesenchymal Tumors of the Jaw"; Dr. P. Meyer: "Fibrous Dysplasia".)

Tuesday, July 7—Wednesday, July 8

Society for the Study of Fertility (at the University, Liverpool).—Annual Conference.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Glaxo Research Fellowship in Immunology at the Wright-Fleming Institute of Microbiology—The Secretary, St. Mary's Hospital Medical School, Paddington, London, W.2 (July 10).

Lecturer in Civil Engineering (with honours degree in civil engineering, or equivalent qualifications, and professional or industrial and teaching experience)—The Director, Robert Gordon's Technical College, Aberdeen (July 10).

Head of the Science and Metallurgy Department at the Constantine Technical College—The Director of Education, Woodlands Road, Middlesbrough (July 11).

Lecturer in Applied Chemistry (with honours degree or equivalent, and teaching and industrial or research experience)—The Principal, Royal Aircraft Establishment Technical College, Farnborough, Hants (July 11)

Mycologist (Scientific Officer Grade) and a Crop Physiologist (Scientific Officer Grade)—The Secretary, Scottish Horticultural Research Institute, Mylnefield, Invergowrie, Dundee (July 11).

Assistant Lecturer in Department of Botany—The Registrar, University College, Hull (July 15).

Honours Graduate (with special interest in Plant Physiology and Physics) for research work in the Pomology Section on frost damage to fruit plants—The Secretary, East Malling Research Station, Maidstone, Kent (July 15).

Bashforth Chair of Mathematical Physics in the Royal Military College of Science, Shrivenham—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4222/53 (July 16).

Biologist (preferably Ph.D.; considerable experience in conducting bioassays and in the care of laboratory animals is required) to run the animal laboratory of the Endocrine Unit at Chelsea Hospital for Women—The Secretary, Queen Charlotte's and Chelsea Hospitals, 339 Goldhawk Road, London, W.6 (July 17).

Assistant Lecturer (with degree in science or dairying and, preferably, with experience in the dairy industry) in Dairying—The Registrar, The University, Reading (July 18).

Assistant Lecturer in Zoology—The Secretary, Birkbeck College, Malet Street, London, W.C.1 (July 18).

International Paints Research Fellowship for biological and chemical research, including research with radioactive substances—The Secretary, Marine Biological Association, The Laboratory, Citadel Hill, Plymouth (July 18).

Scientist (Grade 3) (with good honours degree in geology or chemistry, and some experience or special interest in preparing scientific papers and reports) in the Coal Survey, headquarters staff, London—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/644 (July 18).

University Demonstrator in Physical Chemistry—Dr. F. B. Kipping, Chemical Laboratory, Cambridge (July 18).

Head of the Department of Mechanical Engineering—The Registrar, College of Technology, Suffolk Street, Birmingham 1 (July 20).

Soil Conservation Officers (with degree in conservation, agriculture or agricultural engineering), Southern Rhodesia Government—The Secretary, Rhodesia House, 429 Strand, London, W.C.2 (July 20).

Chair of Zoology and Applied Entomology in the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (July 23).

District (Forest) Officers (with a university degree in forestry, a university diploma in forestry, or a postgraduate degree in a forestry subject) for service in Great Britain—The Secretary, Civil Service Commission, 6 Burlington Gardens, London, W.1, quoting 146/53 (July 23).

Demonstrator (with good honours degree and some research experience) in the Department of Physics—The Dean of the Medical College, St. Bartholomew's Hospital, West Smithfield, London, E.C.1 (July 25).

Experimental Officers and Assistant Experimental Officers (with H.S.C. (Science) or equivalent) at the Atomic Energy Research Establishment, Harwell, for work in physics, chemistry, engineering, chemical engineering and metallurgy—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.283/53A (July 25).

Oil Geologist (with considerable experience in the oil industry on production problems, including the consideration of schemes for the large scale development of oil, and familiarity with the regulations governing oil concessions and, preferably, with university degree) in the Ministry of Fuel and Power—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4221/53 (July 30).

Analytical Chemist, Senior Experimental Officer grade (with degree in chemistry or equivalent qualification and experience in analytical work) to collaborate with plant breeders and grassland agronomists in the routine analysis of plant material used in breeding and research work and to take charge and responsibility for the establishment of a chemical laboratory—The Secretary, Welsh Plant Breeding Station, Penglais, Aberystwyth (July 31).

Assistant Lecturer in Psychology with special reference to general and experimental psychology (with honours degree in psychology or equivalent)—The Secretary, University College, Gower Street, London, W.C.1 (July 31).

Physicists (Scientific Officer Class or Experimental Officer Class) in the Ministry of Supply Research and Development Establishments in Malvern, Farnborough, Sevenoaks, and other outstations in southern England (fields of work include aerodynamics and aircraft structures, armaments, instrumentation, radio and radar)—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.170/53A (August 1).

Research Officer in the Biophysics Subdivision of the National Physical Laboratory, Pretoria—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2 (Pretoria, August 1).

Lecturer in Mathematics at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 15).

Scientific Officer (Biochemist) at the Royal Belfast Hospital for Sick Children, for research in problems in children—The Secretary, Queen's University, Belfast (August 15).

Teacher of Coalmining (with degree or diploma in mining engineering, and Colliery Manager's Certificate) in the N.S.W. Department of Technical Education, Sydney—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2 (August 17).

National Research Development Corporation Scholarships in the Computing Machine Laboratory—The Registrar, The University, Manchester 13 (September 1).

Entomologist (with special interest in the Parasitic Hymenoptera) at the Commonwealth Institute of Entomology—The Secretary, Commonwealth Agricultural Bureaux, Farnham Royal, Bucks (September 15).

Scientific Assistant (with honours degree in biological sciences)—The Director, Commonwealth Bureau of Plant Breeding and Genetics, School of Agriculture, Cambridge (September 26).

Agronomist and a Soil Surveyor to work in the Somaliland Protectorate in co-operation with a hydrologist, to select suitable sites for experimental irrigated farms and to prepare the initial layout of the farms—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDR.63/5/03–4.

Assistant Lecturer (male) in the Chemistry Department, to give lectures on soils and fertilizers, and to assist at practical classes—The Bursar, Royal Agricultural College, Cirencester.

Assistant Lecturer and Demonstrator in the Physics Department and an Assistant Lecturer and Demonstrator in the Physiology Department—The Secretary, Queen Elizabeth College, Campden Hill Road, London, W.8.

Chemist at the Ministry of Supply Tropical Testing Establishment, Port Harcourt, Nigeria, to assist in study of effects of tropical conditions on Service materials and equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.286/53A.

Civil Engineers (with recognized university degree or diploma in civil engineering) in the Public Works Department, Nigeria, for work on civil engineering and irrigation projects, rural and urban water supplies, road development, etc.—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDR.112/14/03.

Electrical Engineer for design and specification of electrical equipment for large factories including H.T. and L.T. switchgear, substations and internal installations—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, quoting 470.

Engineers (with recognized university degree or diploma in civil engineering) in the Roads Branch, Public Works Department, Kenya, for investigation, design, construction and maintenance of roads, bridges and aerodromes—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDR.112/7/09.

Entomologist (Biological Control) and an Entomologist (Ecology and Control) for research on the rhinoceros beetle (*Oryctes rhinoceros*) of coconuts—The Secretary-General, South Pacific Commission, Noumea, New Caledonia.

Hydraulic Engineer (with university degree or diploma in civil engineering) in British Honduras, for investigation and development of small irrigation projects, and potable-water supplies (boreholes and wells), and the collection of hydrological data generally—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDR.112/31/02.

Lecturer, Grade I (with good honours degree in engineering, research and industrial experience) in Mechanical Engineering—The Registrar, The University, Nottingham.

Meteorologist (with honours degree in physics or mathematics, and at least seven years experience in meteorological office or meteorological branch of the Royal Navy, with some service in the tropics, and fully conversant with I.C.A.O. procedures) in the Gold Coast, for supervision of Accra Forecasting Office and related work of outstations, etc.—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDR.57/18/02.

Mineralogist (with second-class honours degree, division I in geology, and specialized in mineralogy and petrology, with one year's postgraduate research experience) in the Geological Survey Department, Nigeria—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDR.105/14/04.

ECONOMICS AND HUMAN FACTORS IN NATIONALIZATION

DURING the past two years, the Acton Society Trust has published a series of twelve research papers dealing with various aspects of the nationalized industries of Britain. These objective studies have made it clear that the application of nationalization to industry has raised problems of an entirely different order from those raised by the public boards or corporations, such as the British Broadcasting Corporation, the Central Electricity Board and the London Passenger Transport Board, which we knew before the Second World War. Some problems, such as those of public accountability and control, of size or of decentralization, were encountered in the earlier experiments in public ownership, and to-day call for solutions differing in degree rather than in kind. Others, it is now apparent, are independent of the form of ownership, but may be more acute under public ownership. Moreover, where industry is concerned, mistakes in organization, control or operation can have most calamitous results on the climate of work, as was indicated in a longer study of training and promotion in nationalized industry which the Acton Society Trust has also issued.

Although the Acton Society Trust has given such an admirable lead to objective discussion, the conclusion of this series of research papers does not mean an end to its studies in this field. A further report on the effect of nationalization on the managers of the working units of nationalized industry is expected to be followed by others on the problems of making changes in large-scale industry, and on the human effects of size of unit. Further, investigations of the Acton Society Trust have been followed by a considerable amount of objective discussion of nationalization through the medium of the technical press and in the proceedings of the Select Committee on Nationalized Industries.

What emerges most clearly from much of this discussion is the unreality of some of the political arguments on nationalization. This is largely because the purposes of nationalization and the purposes of a nationalized industry are by no means necessarily the same. The former are political; the latter are economic. Industries exist for economic purposes, and the attachment or not of the label 'nationalized' does not affect those purposes, though it may change, for better or for worse, the whole climate of work in the industry and raise expectations about the functions of the industry and its responsibilities for service to the community.

This has been clear enough throughout the Acton Society Trust studies which, for all the importance rightly attached to the point of view of those engaged in the industry and of securing their understanding and co-operation, have not made the mistake of dealing with the problem as one of theory rather than practice. The right organization, it is accepted, is the one that leads, within the context of public ownership, to the right decisions, not necessarily that which best accords with administrative theory. The right method of accountability or control is that which encourages initiative and efficiency, rather than that which is most convenient for financial accountability; and the test of efficiency in a nationalized industry is economic, not administrative.

Now we have a study of the future of nationalization by H. A. Clegg, Fellow of Nuffield College, and T. E. Chester, of the Acton Society Trust*. In this book, the problem of labour relations in the nationalized industries and the bearing of the organization of the industries upon such relations are dismissed rather briefly, because one of the authors has discussed this theme at length in an earlier book ("Industrial Democracy and Nationalisation". H. A. Clegg. Oxford: Basil Blackwood, 1951). None the less, they write clearly on the confusion of purposes which has sometimes frustrated the work of consultative committees; and the two points which they stress, that if an organization is to be tolerable the worker must have within reach someone who has the power to take decisions, and that the selection of managers for their ability to handle men in the conditions of to-day is of first-order importance, show that the authors do not make a fetish of organization. They do not imagine that the problems of large-scale organization can be spirited away by the device of electing managements. Nevertheless, this well-written book, with its clear and admirable argument, tends to over-simplify the issues and to over-stress the importance of organization. Its concern is essentially with the patterns of organization in the nationalized industries. It does not suggest that any one pattern is necessarily desirable for all the industries that have been or may be nationalized; but it does incline to the view that if the most appropriate and efficient form of organization from the administrative point of view is discovered and applied to each industry, all will be well. The line of approach is to describe objectively the way in which the existing forms of organization came to be developed, whether on doctrinaire or on pragmatic grounds. The existing structures are dealt with in some detail, and the authors then discuss these forms of organization and whether they could be improved. The proposals they make for re-organization are based essentially on the thesis that if we can determine why the nationalized industries have failed to achieve, in a satisfactory measure, the purposes for which the change in ownership and organization was made, we need only to specify what different organization would be better suited to that purpose.

To suggest that the answers to these questions will of themselves settle the future of the nationalized industries is a gross over-simplification and ignores some of the main problems; nor do the authors really appear to believe in this simplification. Although they largely ignore the economic purposes and aspects of industry, their advocacy of the most efficient and appropriate organization for the execution of policy shows that they are aware that both organization and policy must have regard to what is humanly possible. As already noted, in their reference to industrial relations the authors recognize the importance of effective contact between workers and those who have power to take decisions, and in their remarks on the selection of managers they add that there is little sense in putting forward a scheme for re-organizing nationalised industry unless it can be shown that men can be found to make it work.

This question is dealt with at considerable length in the concluding chapter, and besides being one of immediate interest to the scientist or technologist, the discussion well illustrates one of the central propositions on which Mr. Clegg and Mr. Chester base their proposals. "The only criteria," they write (p. 132), "which we can even try to handle are impressions about the effect of forms of organization on those who work in the nationalized industries, and guesses about the probable effect upon them of changes in organization. We assume that there is a connexion between their state of mind and 'efficiency' (measured in terms of quantities, qualities and prices), without being able to demonstrate the existence of the connection." Thus, they do not give an unqualified answer of 'yes' to the questions whether it is not likely that the boards will have found and used the best men available, and whether they are not developing schemes of promotion and training which will open the highest posts to talent wherever in the industry it is to be found. The authors do not discuss some of the obstacles to a satisfactory promotion policy which were noted by the Acton Society Trust, but they do suggest that more could be done to foster and strengthen the desirable human qualities of leadership where they exist, and that more weight could be given to these qualities by selection boards. They also comment that it would be more sensible to construct an organization without national management boards than to hope that some day the supermen needed to run them may be forthcoming.

Such considerations, among others, lead Mr. Clegg and Mr. Chester to advance proposals which would have the advantage that more first-rate men would be available for the posts of operational managers whose status would be enhanced by a reduction in the number of their superiors. This should also make the posts more attractive to first-rate men; and if this happens, industrial relations should benefit handsomely. Incidentally, their proposals, which find further support here in recent management studies by J. F. Scott and R. P. Lynton, would also result in less lavish demands for talent and genius by the nationalized industries, which in itself would assist the best use of talent.

The second proposition on which Mr. Clegg and Mr. Chester base their proposals is also one favouring decentralization and small-scale operation. It is implicit in the foregoing argument that some of the existing weaknesses of nationalized industry are due to failure to fill many of the posts with men of the requisite ability. Even, however, had men of the desirable calibre been forthcoming, on Mr. Clegg and Mr. Chester's second proposition the position would still have been unsatisfactory. This proposition is that the type of organization imposed on the industries nationalized since 1945 is based on the erroneous conclusion that, because some functions of the industries required large-scale organization, all other functions also required large-scale organization.

---

* The Future of Nationalization. By H. A. Clegg and T. E. Chester. Pp. ix+211. (Oxford: Basil Blackwell, 1953.) 12s. 6d. net.

The great merit of the detached and scholarly analysis of nationalization presented in this book is that it demonstrates the fallacy of this view. The authors point out that such an arrangement must result in over-centralization, both because once central bodies have been given over-all responsibility for their industries by Parliament, those with grievances against subordinate authorities will pursue them to the central body or the Minister, and also because the general responsibility of the central bodies leads to a hierarchical organization in which effective decentralization is impossible. Both from the criteria of how people can best work together and achieve the maximum administrative efficiency, and from the practical point of view of finding the managerial ability, they urge that smaller units for general management are desirable. Parliament, they suggest, should decide what functions can and should be exercised over an area wider than the individual undertaking, and place responsibility for these functions—and for these alone—upon appropriate regional and national authorities. In other words, we are brought back to the second principle that, in decisions to centralize authority, the *onus probandi* should always rest with those urging centralization. The book is thus a challenge to constructive thought and to further investigations as to the design of such appropriate authorities, though some indication is given with regard to promising lines; the suggestions at least merit examination and discussion in an atmosphere as free from political prejudice as the spirit in which they are advanced. They are not proposals for denationalization; indeed, the authors believe that nationalization is compatible with small-scale operation. Nor do they exaggerate the importance of the proposals or the magnitude of their probable effects. They believe that improved organization can lessen the likelihood of disputes and facilitate their handling.

This book should certainly encourage a more objective examination of the future of nationalization itself, as well as of the organization of the nationalized industries. It should equally discourage any over-optimistic view that present difficulties will work themselves out if the industries are left alone. It is pointed out, for example, that since under directed training schemes potential managers gain practical experience under existing managers, there is danger that bad practices may be perpetuated, and again that some organizations are so constructed that good habits are discouraged and bad habits develop without restraint. As in the Acton Society Trust reports, it is recognized that decentralization is primarily a problem of the adjustment of human relations. Parliament, it is suggested, should lay down a clear and reasonable set of rules for each nationalized industry—a set of rules which would support good habits as the industries grow to strength and maturity. This is reasonable doctrine; but, even if the appropriate form of organization is discovered and adopted, it will still not ensure that the right policies are adopted, and it is above all on the formulation and adoption of the right policies that the future of the nationalized industries depends. Here is where further inquiry is needed, and how deep and wide it may have to go is sufficiently illustrated by reference to the Ridley Report on the national policy for the use of fuel and power resources in Britain. That Report placed the responsibility for the formulation of policy fairly and squarely on the Minister of Fuel and Power. The Ridley Committee regarded the functions of co-ordination and control of policy as the main reason for the existence of a Minister of Fuel and Power. Failure to ensure that the nationalized industries are administered in the national and not in a sectional interest is not a failure of organization, but a failure of ministerial leadership for which successive Governments must accept responsibility. Indeed, so far from having formulated a national policy, the present Minister could only say in the House of Commons on May 18—nine months after the Ridley Committee reported—that he hoped to make a statement soon after the House reassembled from the Whitsuntide and Coronation recess; this sufficiently demonstrates that much more is required than the discovery and use of means of making national ownership and national planning compatible with small-scale operation. Mr. Clegg and Mr. Chester point in the right direction; but something more than fresh thinking about the organization of the nationalized industries is required to secure their efficient working, and the success of what is admitted by both political parties to be a large-scale experiment. Mr. Clegg and Mr. Chester may have limited their survey too severely and over-emphasized one aspect of the problem. The solid merits of their book may none the less stimulate the wider thinking and inquiries that are necessary for ensuring that the appropriate organization, once determined, is entrusted with the right policy to execute.

THE COMMUNITY CONCEPT IN ECOLOGY

Natural Communities

By Lee R. Dice. Pp. xi+547. (Ann Arbor, Mich.: University of Michigan Press; London: Oxford University Press, 1952.) 45*s*. net.

THE author says that the purpose of his book is "to describe the more important methods and concepts of one division of biology, that dealing with natural communities. If the reader gains a better understanding of the importance of ecological communities to the world of life, I shall be pleased. It is my earnest hope moreover, that this exposition may stimulate further investigation in this complex and as yet little understood field of biology". This quotation is important because it expresses exactly not only the function of the book but also the impression it has made on at least one reader. It also shows how well the author has succeeded in his task, for the book may indeed be regarded as one of the most complete statements of ecology that has so far appeared, and one, it should be added, written with quite exceptional clarity of expression.

Very properly this considerable book is largely a monument to the enormous amount of excellent and untiring work which has gone to make the modern subject of ecology; but it is written in so balanced and judicious a way that it also shows quite clearly how much the subject still labours under disabilities inherent in our usual methods of studying the inter-relations of living things. We should neither magnify nor ignore imperfections, but many will agree that there is, about much ecology, an undefinable lack of reality which suggests something at fault in our methods of approaching it, and since this is also the conclusion to which readers of Dr. Dice's book are likely to come, it is perhaps most useful here to notice how his presentation helps to throw light upon the causes as well as the symptoms of this *malaise*. It would seem that they are basically three.

One is that ecologists have not yet really reached the point of regarding the ecologic community as a single coherent unity. This is chiefly due to that specialization which still makes biologists either botanists or zoologists; but this is not all, and while botanists, secure in the knowledge of the fundamental role of their subject, tend to ignore the animal side of ecology, the zoologists show a not unnatural tendency to try, by a similar process, to balance the two, and this almost inevitably gives a sense of unreality to the whole. Plant life and animal life are neither strictly comparable nor mutually incompatible; they are the two variable ingredients which make up the biological scene. The terrifying list of qualifications suggested by the author as the necessary equipment of the perfect ecologist suggests that this problem may be difficult to solve, but at least he indicates the direction of its solution.

Another cause is the difficulty of getting free from the anthropocentric point of view. Especially it seems difficult to realize, and consistently to maintain the realization, that animals and plants in natural communities may not react upon one another in the same fashion and with the same motivation as do members of human societies, and that some of the methods which may be of value in the study of human economics are not equally applicable to the study of non-human ecology. In this connexion the notably guarded attitude of Dr. Dice towards some aspects of statistical ecology will win the approval of many.

The third and deepest reason for dissatisfaction is our failure to abandon outmoded biological conceptions, and this has two main aspects. More important, because of its profound significance to the world in general, is what may be called the 'Nature red in tooth and claw' fallacy. One would imagine that the influence which such a belief has had on human affairs in the past half-century would at least raise doubts about its validity; but even more odd is the apparent continuing failure to admit that the very existence of a science of 'natural communities' belies it, for if Nature was indeed as the poet described it, its condition would be chaotic and in a perpetual state of disequilibrium. If there were nothing else to thank Dr. Dice for, there is the support his book gives to the view that Nature is essentially a state of beautiful and delicate balance to which each and every member makes its due, but only due, contribution.

Inextricably involved with this fallacy is the vexed question of that seemingly immortal phoenix 'adaptation'. One suspects that the author views this side of his theme with some reluctance, for it is here, when he tries to deal faithfully with this treacherous subject, that he loses his usual sureness of touch. Like many others, he tries as best he can to maintain the position by depicting biological 'adaptation' as something far from the general understanding of that word; but the inconsistencies into which his quite proper attempt to deal with this matter force him are at once the chief weakness in the book and the clearest comment on the adaptationist point of view. But these imperfections are not of his making. They are part of the still generally current story, and it is the extraordinarily undeniable way in which Dr. Dice's book exposes the real value of such things that makes it so important a contribution to the better understanding of ecology. RONALD GOOD

DANA'S "MINERALOGY"

The System of Mineralogy of James Dwight Dana and Edward Salisbury Dana, Yale University, 1837–1892

Seventh edition, entirely rewritten and greatly enlarged, by Charles Palache, the late Harry Berman, and Clifford Frondel. Vol. 2: Halides, Nitrates, Borates, Carbonates, Sulfates, Phosphates, Arsenates, Tungstates, Molybdates, etc. Pp. xi+1124. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1951.) 120*s*. net.

Dana's Manual of Mineralogy

Sixteenth edition, revised by Prof. Cornelius S. Hurlbut, Jr. Pp. viii+530. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1952.) 48*s*. net.

THERE can be few scientific text-books published more than a hundred years ago that are still 'alive', but James Dwight Dana's classic, "System of Mineralogy", which first appeared in New Haven, in 1837, is one. It was even then a considerable work of 572 pages, but the author would be a proud man to-day could he see his first book in its latest form. It is now more than fifty years since his mortal remains were laid to rest, but it can truly be said that his soul goes marching on.

The last edition of the "System", the sixth, was published by his son, Edward S. Dana, in 1892, and this was kept up to date by the issue of three supplements. In 1915 the decision was made to prepare an entirely new edition, and the work was entrusted to the late Prof. W. E. Ford, of Yale University. Since then many specialists, too numerous to mention, have assisted in preparing the latest edition; and financial assistance has been received from funds at the disposal of the Geological Society of America and Harvard University. A word of praise is also due to the publishers, John Wiley and Sons, Inc., of New York, who have been associated with the book since 1844, when they published the second edition; they have agreed to take no profit from the sale of the book until the grant from the Geological Society has been repaid.

The first volume of the new edition appeared in 1944, and dealt with the elements, sulphides, sulpho-salts and oxides. Vol. 2, the volume at present under notice, is dated 1951 and includes halides, nitrates, borates, carbonates, sulphates, phosphates, arsenates, etc. The silicates will be described in a third volume, yet to appear.

In Vol. 2, not only has the text been enlarged and the presentation modernized, but also every detail has been thoroughly revised in the light of the great amount of research into the mineralogical and crystallographic sciences carried out since the last edition appeared. This is a book which needs no recommendation to mineralogists, and is likely to remain a standard work of reference for many years.

Dana's smaller "Manual of Mineralogy", intended for students, amateur collectors and mining geologists, has had an almost equally long and distinguished career, the first edition having appeared in 1848. The main changes in the latest edition are the inclusion of some introductory matter of a general character and the addition of a separate section on crystal chemistry.

FOOD SUPPLY AND CONSUMPTION IN GREAT BRITAIN

Britain's Food Supplies

By Dr. K. G. Fenelon. Pp. ix+212. (London: Methuen and Co., Ltd., 1952.) 15*s.* net.

On three counts at least this is a useful and timely book. Since he was, for a while, director of statistics and intelligence at the Ministry of Food, Dr. K. G. Fenelon is well fitted to select the contents of the twenty-seven pages of tables, with which it closes; they are conveniently arranged for reference. The story of British war-time and post-war food problems, which consumes about half his space, is as concise and readable a description as one could find; it is the kind of thing that should be compulsory reading for all students of dietetics and catering. But flowing through the book (I am not sure how far Dr. Fenelon is aware of it) runs a strain of dramatic irony, as Britain's food position is traced from its eighteenth-century days of virtual self-sufficiency to the chronic crisis in which it is now involved.

Carefully studied with this in view, the work is a salutary one. The text is announced in the opening sentences: "Most countries produce the bulk of their own food. Only a very few import more than a third of their total food supply and among these Britain is outstanding as by far the largest buyer, taking before the Second World War no less than 40 per cent of the world's total trade in food and animal feeding stuffs". On the last page the narrative concludes with a quotation from Adam Smith; if Britain, says Smith, cannot achieve an all-round increase in productivity, then she will have to "endeavour to accommodate her future views and designs to the real mediocrity of her circumstances".

The interval between these sentences is filled with illustrative facts and figures. For more than fifty pages Dr. Fenelon reveals the slowly increasing dependence of Britain upon world food markets; incidentally, he shows the corresponding dependence of world food markets upon the British consumer. Thus, for example, "Britain was [before the Second World War] far and away the largest world buyer of meat and bacon, taking something like three-quarters of the world's export trade of some 2 million tons annually" (p. 50); or again, "Britain imported about four-fifths of the world's exports of butter and about half of those of cheese and eggs" (p. 51). But later comes the irony of shrinking supplies, and the gradual diversion of products. What of Australia? "Before the war, 70 per cent of the wheat crop was exported, whereas in 1947–48 only 43 per cent went abroad. Australia's contribution to world food supplies will be a considerable factor during the next decade or so, but beyond that period it appears doubtful if there will be any large exportable surplus. During the last twenty years population has risen by over 2¼ millions. . . ." (p. 142). And South Africa? "Meat was exported before the war from the Union and Southern Rhodesia, but Union meat exports have now ceased, and those from Rhodesia are likely to disappear before long. The chief reason is increased consumption per person and this is also the case with sugar and wheat. The Union now needs to import 40 per cent of its wheat and flour requirements . . ." (p. 144).

There are brief but useful chapters on the various international schemes and agencies for controlling or raising food production; and these, together with the survey of world food supplies and consumption-levels, serve to set the British position in its global context. The bibliography and the index are satisfactory.

F. Le Gros Clark

OUTLINE OF RADIO ASTRONOMY

Radio Astronomy

By Prof. Bernard Lovell and Dr. J. A. Clegg. (Frontiers of Science Series.) Pp. 238+8 plates. (London: Chapman and Hall, Ltd., 1952.) 16*s.* net.

Major advances in science often come about when a technique developed for one type of investigation is applied to another. Radio astronomy is an excellent example of this. During the past seven years the use of radio methods has revealed the presence of hitherto unsuspected meteor streams and has enabled the velocities of meteors to be measured; it has added considerably to our knowledge of the solar corona both under quiet and disturbed conditions; and it has revealed the existence of numerous 'radio stars' which emit strongly in the radio-frequency portion of the spectrum.

"Radio Astronomy", by A. C. B. Lovell and J. A. Clegg, gives an admirable and concise account of this new work. The book is in the series "Frontiers of Science" edited by Prof. Lovell and admirably fulfils what is stated to be the aim of that series: "the filling of a gap in Scientific publications between the very elementary expositions and the specialist text books". By a remarkable feat of compression the authors have succeeded in presenting, in successive thirds of this small book: the essential ideas of positional astronomy and radar techniques; a most readable and instructive account of what has been achieved in the study of meteors by radio methods; and a summarizing account of the results achieved in the study of radio waves emitted by the sun and other bodies outside the earth. Anyone with a knowledge of physics to the standard of 'university entrance' will find the book most instructive and readable, and it will be especially useful to those working in other branches of physics and to anyone starting research in radio astronomy.

In a book on radio astronomy it is perhaps a little surprising to find so large a proportion devoted to the radio detection of meteors. This part, which deals with a field of knowledge in which the authors are themselves leaders, is most illuminating and stimulating, and is the best part of the book. The part on radio emission from extra-terrestrial bodies (what is usually called radio astronomy) is, by comparison, less impressive. It naturally takes the form more of a catalogue of the work of others, without much attempt at criticism, but it is an excellent and readable catalogue.

The clear and precise introductory chapters on positional astronomy and on radar technique and aerials could well be read by anyone interested in these subjects, quite apart from their application to radio astronomy. I feel that it is unfortunate that the excellent chapter on radar methods is marred by the quoting of particular units after algebraic expressions which are correct in all system of units. Although I know that this failing is common to those who use m.k.s. systems, I nevertheless consider it is wrong in principle and wish to make my protest against it. J. A. RATCLIFFE

SOIL PHYSICS IN AGRONOMY

Soil Physical Conditions and Plant Growth

Compiled by the Joint Committee on Soil Tilth, American Society of Agronomy, American Society of Agricultural Engineers. Byron T. Shaw, Editor. (Agronomy, a Series of Monographs, Vol. 2.) Pp. xv+491. (New York: Academic Press, Inc., 1952.) 8.50 dollars.

FOR want of a better definition, agronomy can be regarded as agricultural technology in which the emphasis in research is on "How?" rather than on "Why?". This monograph, written by ten authors and dealing with five aspects of the interrelation of soil conditions and plant growth, conforms easily to such a definition, for it presents detailed surveys of existing knowledge supplemented by extensive lists of references that enhance the value of the book. The sections differ in length and quality. The first, on the soil as a physical system (forty-two pages), gives a background for those who need it; the second, on mechanical impedance and plant growth, fills thirty pages—more than enough to reveal our complete ignorance of the topic. Then comes an admirable survey of soil water (a hundred and eighty pages), which, though based mainly on American experience, remains aware that there are water problems elsewhere in the world and that much useful work has been done toward solving them. The section on soil aeration (fifty pages) satisfies an important need for a dispassionate survey of an aspect of soil physics that is usually discussed in somewhat mystical terms; and the long final chapter on soil temperature (a hundred and seventy-eight pages) very reasonably brings in discussions of the effect of air temperature too. Many aspects of the problem are considered; but, whereas the length of the chapter on soil water is a measure of the importance of water in plant growth, the length of this chapter is probably a result of the ease with which soil temperature can be measured.

There is much to criticize in the book, but nearly all such criticism is of the primary authors and not of the compilers; and this is the cause of a slight feeling of disappointment. Though the personal touch does appear here and there, it is too infrequent, possibly because the compilers have had behind them a panel of twenty-five experts who reviewed the manuscript and offered comments on all or parts of it. Some day, perhaps, out of this book and from among these compilers another book may grow, a more single-minded book based on ideas rather than on facts, with a title "Soil Conditions in the Physics of Plant Growth".

Printing and binding are good, but the price is high. A copy—or copies, for it will be well used—should be in the library of every institution that encourages research or teaching in agricultural science. H. L. PENMAN

TABLES OF PERCENTAGE COMPOSITION OF ORGANIC COMPOUNDS

Prozenttabellen organischer Verbindungen (Tables of Percentage Composition of Organic Compounds)

C—H—O, C—H—N, C—H—O—N, C—H; C—H—S, C—H—O—S, C—H—N—S, C—H—O—N—S. By Dr. H. Gysel. Pp. xxii+637. (Basel: Verlag Birkhäuser, 1951.) 125 francs.

THE ancillary services provided by the micro-analyst, the spectroscopist (ultra-violet and infra-red) and the X-ray crystallographer have made the life of the modern organic chemist seem feather-bedded by comparison with that of his older colleagues. Dr. H. Gysel's tables supply a further aid which, although not of the same quality as the services mentioned, will effect a considerable saving of time spent on purely mechanical processes. Apart from a short explanatory preface, in three languages, the book consists entirely of tables. The percentage composition to 0·001 per cent has been calculated for about seventy thousand formulæ. The figures have been rounded off to two decimal places, and the molecular weights are also given. At a rough estimate the figures represent upwards of a quarter of a million calculations. It is easy to accept the statement that "this book involved a considerable amount of work".

The tables relate to CH compounds up to $C_{[illegible]}$, CHO compounds to $C_{[illegible]}$, CHN compounds to $C_{[illegible]}$, and CHON compounds to C_{40}. It is not easy to follow the logic of the decision to include C_{40}–$C_{[illegible]}$ compounds "only insofar as they have already appeared in the literature". The chemist who uses these tables will often be more interested in compounds which have not been described previously. For the compounds included in the tables, it is possible to determine, by inspection, the percentages of the elements, including oxygen. To assist in the calculation of the composition of compounds containing other elements (except sulphur, which can be dealt with from the simple relationship of its atomic weight to that of oxygen) supplementary tables give multiples of the atomic weights of common elements and of the weights of simple atomic groups. There are also tables of the specific gravity of nitrogen at various temperatures and pressures, and of the logarithms of these values.

By the use of these tables I have been able to detect typographical errors that have crept in during the various stages of drafting and typing papers, and some errors have been found even in composition figures published in the chemical journals. Whether the tables are "almost free from errors" as claimed can only be determined by much more prolonged use. It is unfortunate that the high price of the tables will restrict their availability. J. W. COOK

Literature for an Age of Science

By Prof. Hyman Levy and Helen Spalding. Pp. x+250. (London: Methuen and Co., Ltd., 1952.) 15s. net.

THIS book is a joint venture by two people whose disciplines lie respectively in the fields of science and literature. At the outset, it can be said that their work is both timely and important. It extends into a larger sphere, and away from the detailed mechanism of criticism—the rational treatment of literature such as was suggested by I. Richards in his "Principles of Literary Criticism".

Prof. H. Levy and Helen Spalding attempt to see literature as a feature of social life and to judge its importance and its potentialities within this life. The functions of poetry, drama and the novel are reviewed in relation to modern sociological ideas. Science and the arts are aspects of one venture; they should be complementary and mutually supporting. But at present we are far from realizing this ideal: a scientist or a technologist can express the quality of truth in his work and can thrive, whereas a writer who expresses an important but unpalatable truth cannot expect encouragement. Truth in science can be commercially useful, but truth in literature cannot always be. Commerce is not concerned with the whole of truth, and yet human beings are. Science, with the material rewards and the intellectual satisfactions heavily weighted in its favour, tends to attract to itself the intellectual vitality of society to the relative impoverishment of the arts.

There are few inducements to help equalize the flow of creative energy in all directions, for the pressures that are responsible for the actual distribution of this energy are in no way consciously controlled or directed but are left to the random play of social forces only dimly apprehended. Even the academic rewards given for creative work in science are not given for creative work in literature, though the desiccated dissection (not even worthy of printing), of a minor poet, may bring its producer a Ph.D.

Nevertheless, this near-Marxist view of literature presented by the authors will be considered partial, if not perverse, by most readers. It is notoriously lacking in human individual qualities, it knows nothing of ultimate values and it tends to be unimaginative, arid and unentertaining.

W. L. SUMNER

Practical Organic Chemistry

By Dr. Frederick George Mann and Dr. Bernard Charles Saunders. Third edition. Pp. xv+466. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1952.) 18s. net.

IN the third edition of this popular manual, the authors have made a thorough revision of the text, based on sixteen years of experience of its use in the laboratory, and have somewhat raised the general standard by an increase in the range of the preparations and an extension of the section dealing with identifications, greater emphasis now being placed on the preparation of crystalline derivatives. A new short section, which should prove particularly useful in view of the increased cost of chemicals, describes the use of apparatus for small-scale manipulations. The macro methods of estimation of carbon, hydrogen and nitrogen have at last disappeared, and have been replaced by a section on semi-micro methods of analysis.

Descriptions of methods of manipulation and experimental directions throughout are extremely clear and precise, and the theoretical notes preceding each experiment should enable the student to understand the general principles involved. The scope of the book is perhaps still too limited to justify the authors' claim that it should now cater fully for the needs of students working for honours degrees; it certainly meets admirably the requirements of pass-degree students, and the price, although about double that of the second edition, is still very moderate by current standards.

C. BUCHANAN

Hobhouse Memorial Lectures, 1941–50

Pp. vii+268. (London: Oxford University Press, 1952.) 17s. 6d. net.

THIS collection of lectures by distinguished social scientists and philosophers shows that, though Hobhouse's system of thought and belief has been severely shaken in the troubled years that have succeeded his death, efforts are still being made to follow many of the lines he laid down. C. P. Scott, an intimate colleague and friend, wrote that "his deepest instinctive belief and hope were in human progress", and that his life and work represented "an imposing expression of intellectual power allied to an almost childlike friendliness". All these things have since come under criticism, and it will be reassuring to many to find evidence in the Memorial Lectures that the kinds of intellectual courage and optimism for which Hobhouse is remembered are not yet extinguished.

The most impressive of the lectures, which shows the deepest knowledge of Hobhouse's work, and makes an attempt to translate his ideas into the mould of present-day thinking, is by Prof. H. L. Beales, who defends the constructive liberalism with which Hobhouse was associated from the attacks of critics of 'planning'. Hobhouse himself would also have been greatly interested by Dr. C. E. Raven's re-examination of the relationships between religion and science, which, as he points out, was very relevant to Hobhouse's central interests and is of supreme importance at the present time. Many issues which would have excited Hobhouse's mind are, moreover, touched on by Prof. Gordon Childe in his lecture on "Social Worlds of Knowledge".

Beautifying India

By M. S. Randhawa. Pp. xviii+224+23 plates. (Delhi and Bombay: Rájkamal Publications, Ltd., 1950.) 15 rupees; 28s.

THIS is virtually a miscellany on art, science and æsthetics in which the author is concerned with the problem of beautifying his native land—this to coincide with what he hopes and believes to be the inception of a period of prosperity. While one may not agree with all the author's views and opinions, one cannot fail to appreciate his enthusiasm, the lucid exposition of his views, and his evident sincerity. Like other tropical regions, India needs beautifying. In the author's view, this will only come about by a general awakening of interest and a conscious effort to bring to bear the right kind of action—that is, a conscious planning of the flora and fauna with the object of creating a pleasing pattern of colour throughout the land. Bio-æsthetic planning is essentially planned ecology, and, in its application to the Indian scene, would take the form of a widespread planting and appropriate massing of ornamental flowering trees. On this subject, the author has brought together much useful information which may well have a wider application to tropical regions in general.

SCURVY IN RETROSPECT

By Dr. LESLIE J. HARRIS
Dunn Nutritional Laboratory, Cambridge

TWO hundred years ago, in 1753 at Edinburgh, was published Lind's "Treatise on Scurvy"—or to give it its full title: "A Treatise of the Scurvy, in Three Parts, Containing an Inquiry into the Nature, Causes and Cure of that Disease, together with a Critical and Chronological View of what has been Published on the Subject". This is almost the first book to deal exclusively with what we should now call a vitamin-deficiency disease. But it is not quite the first, because in 1650 Glisson of Cambridge had published his famous work on "Rickets"; and five years earlier still Whistler from Oxford had brought out, in Leyden, as his M.D. thesis, the less well known but important "De morbo puerili Anglorum quem patrio idiomate indigenæ vocant, The Rickets".

To mark the bicentenary of Lind's noted book, and imbued no doubt with a due sense of civic pride, Drs. C. P. Stewart and A. P. Meiklejohn, of the University of Edinburgh, recently organized a series of celebrations in that city. These included: a scientific conference on vitamin C, held under the auspices of the Nutrition Society of Great Britain and attended by leading experts from other parts of the world; an honorary degree ceremony, together with other academic and social occasions; and the re-issue of Lind's "Treatise", complete with new explanatory notes.

Dr. C. P. Stewart and Dr. D. Guthrie, who have been responsible for the editing of this reprint of Lind's first edition, have done their work admirably. In this volume[*], in addition to the careful re-issue of the "Treatise" in modern typography, there are included also contributions by C. P. Stewart (a description of "The Third Edition of the *Treatise*"), Surgeon Vice-Admiral Sir Sheldon F. Dudley ("The Lind Tradition in the Royal Naval Medical Service"), D. Guthrie and A. P. Meiklejohn ("James Lind and Some of His Contemporaries"), C. P. Stewart ("Scurvy in the Nineteenth Century and After"), E. L. Hirst ("The Chemistry of Vitamin C"), and A. P. Meiklejohn, C. P. Stewart and R. Passmore ("The Rôle of Ascorbic Acid in the Human Body"). Every worker on vitamins, and every medical historian, can now be proud to possess, on his own bookshelf, a copy of the famous Lind "Treatise".

It is sometimes said that Lind was the first to discover how scurvy could be cured or prevented, namely, by the use of orange or lemon juice. This is a slight, if pardonable, exaggeration. Others before Lind had, in fact, recorded how scurvy might be controlled by the consumption of such 'antiscorbutics' as a decoction of spruce pine needles (Jacques Cartier, 1535), or by oranges and lemons (Sir Richard Hawkins, 1593). Most notably, in 1601, Sir James Lancaster had introduced into the ships of the East India Company the regular use of oranges and lemons as a sure preventive of this dreaded scourge of mariners. Then, during the seventeenth and eighteenth centuries, many others repeatedly confirmed the fact that fresh fruits and vegetables were effective in curing or preventing scurvy (for example, Woodall, 1639, Kramer, 1739).

But, as with so many scientific discoveries, what had been discovered was later to be forgotten and had to be re-discovered. Knowledge generally grows little by little, by developing what is already known rather than by some spectacular, unpredicted leap into the unknown. Just as no one individual can claim to have been the first to discover the existence of vitamins or to recognize the nature of the vitamin-deficiency diseases, so the knowledge of how to prevent scurvy empirically by means of fresh fruits or vegetables, or other fresh foods, emerged little by little.

Perhaps the juster claim to make on Lind's behalf is that he was the first, or one of the first, to carry out an accurately controlled clinical test, to prove conclusively how scurvy could be cured. To say that is not to belittle Lind's fame, but perhaps to enhance it.

Lind's own account of his test has been more than once quoted before, but bears repetition:

> "On the 20th May, 1747, I took twelve patients in the scurvy, on board the *Salisbury* at sea. Their cases were as similar as I could have them. . . . Two of these were ordered each a quart of cyder a-day. Two others took twenty-five gutts of *elixir vitriol* three times a-day. . . . Two others took two spoonfuls of vinegar three times a-day upon an empty stomach. . . . Two of the worst . . . were put under a course of sea-water. . . . Two others had each two oranges and one lemon given them every day. . . . The two remaining patients, took the bigness of a nutmeg three times a-day, of an electuary recommended by an hospital surgeon. . . .
>
> "The consequence was, that the most sudden and visible good effects were perceived from the use of the oranges and lemons; one of those who had taken them, being at the end of six days fit for duty. . . . The other was the best recovered of any in his condition; and being now deemed pretty well, was appointed nurse to the rest of the sick. . . ."

Elsewhere, he writes:

> "Some persons cannot be brought to believe that a disease so fatal and dreadful can be prevented or cured by such easy means. They would have more faith in some elaborate composition dignified by the title of an antiscorbutic golden elixir or the like. . . . Facts are sufficient to convince the unprejudiced. It is no easy matter to root out old prejudices or overturn opinions which have acquired an establishment by time, custom and great authorities."

In Lind's own day it was rightly said that scurvy had done more to reduce the fighting strength of the Royal Navy than enemy action and shipwreck combined. Lind himself, venerated as the 'father of nautical medicine', was the medical director of the Naval Hospital at Haslar, near Portsmouth, during 1758–83. This was, and still is, the largest hospital ever built. In his time, one-quarter of all the patients in it were suffering from scurvy.

The havoc which had been wrought by the disease among navigators is apparent from records going back to the fifteenth and sixteenth centuries. For example, when in 1498 Vasco da Gama had sailed around the Cape of Good Hope, a hundred of his men had perished from scurvy, out of a crew of a hundred and sixty. In 1593, Admiral Sir Richard Hawkins mentioned that ten thousand seamen had died from scurvy within his own personal experience. On one occasion a Spanish galleon had been found adrift at sea, its entire crew dead from scurvy.

---

[*] Lind's Treatise on Scurvy. A Bicentenary Volume containing a reprint of the first edition of "A Treatise of the Scurvy by James Lind, M.D.", with Additional Notes. Edited by Dr. C. P. Stewart and Dr. Douglas Guthrie. Pp. xi+440+4 plates. (Edinburgh: At the University Press, 1953.) 45s. net.

But for centuries scurvy was of common occurrence not only among seafarers and explorers and armies in the field but also among civilian populations in most regions of Northern Europe. The reason for this was that throughout the dark months of winter vegetables and fruits were unobtainable. The principal factors which led ultimately to the decline of scurvy were the introduction of the potato into Europe, and the development of modern methods of transport—and, in more recent times, to the growth of exact, scientific knowledge about the existence of, and the properties of, the anti-scurvy vitamin.

After Lind's time the puzzle of scurvy was to be unravelled in gradual stages, both on the practical and on the theoretical side. In 1772, Captain Cook's voyage around the world owed its success to the measures taken by the Admiralty to protect the sailors from scurvy. Captain Cook himself was awarded the Copley Medal of the Royal Society in 1776 for his account of how the disorder had been prevented on board his ship. In 1804, at the instigation of Sir Gilbert Blane, regulations were introduced into the British Navy enforcing the consumption of daily rations of lemon juice. In consequence, the incidence of scurvy at the Haslar Naval Hospital fell from 1,457 cases in 1780 to vanishing point by 1806.

Later, the unwarranted substitution of preserved lime juice (unhappily inactive) for the fresh lemon juice (a potent antiscorbutic) was to lead to misunderstandings and misfortunes. The disaster which befell Captain Scott's expedition to the South Pole in 1912 can be attributed largely to a failure to supply active antiscorbutic articles of food.

Then again, during the First World War, outbreaks of scurvy still occurred in Britain: fifty cases were reported at a poor-law infirmary in Glasgow, eighty-two cases in a prison camp in another part of Scotland, and sixteen cases at an infirmary in Newcastle. The cause was considered to be a national shortage of potatoes; but a failure to apply existing knowledge might as justly be blamed.

As late as the beginning of the present century, infantile scurvy was still rife among bottle-fed babies, as a result of the wide use of sterilized or boiled milk, or of farinaceous milk substitutes, in place of fresh milk. The modern infant welfare movement, with its insistence on the provision of antiscorbutic supplements, has changed all that. Nevertheless, in a recent survey at the Johns Hopkins Hospital in Baltimore, Maryland, U.S.A., microscopic evidence of scurvy was found to be present, *post mortem*, in 31 per cent of those babies examined, between the fifth and eleventh month of age, who had been fed on cows' milk alone.

Scientific, as distinct from empirical, knowledge about scurvy starts from 1907. In that year—following the earlier recognition that beriberi could be produced experimentally in birds, and was a disease of deficiency—Holst and Frölich, in Oslo, stumbled across experimental scurvy in guinea pigs, and they were quick to recognize it as another deficiency disease.

Writing in 1906, Hopkins had already referred to scurvy as a disease of which "for long years we have had knowledge of a dietetic factor", and he rightly added that the error in the diet was "still obscure" but "certainly of the kind which comprises the minimal qualitative factors". (And one recalls here, too, that as long previously as 1840 another far-sighted writer, G. Budd, had predicted that scurvy was due to the "lack of an essential element which it is hardly too sanguine to state will be discovered by organic chemistry or the experiments of physiologists in a not too distant future".) By 1912, Funk was able to postulate the existence of a distinctive anti-scurvy "vitamine", and to enumerate four separate disorders, namely, scurvy, beriberi, rickets and pellagra, as being "vitamine" deficiency diseases. In 1920, J. C. Drummond introduced the current alphabetical nomenclature, the letter "C" being reserved for the then unidentified anti-scurvy factor.

The earliest attempts to isolate vitamin C, by Zilva and by others, were rendered difficult by its instability and its power to undergo reversible oxidation. However, in 1928, the Hungarian biochemist, Szent-Györgyi, then working in Cambridge, isolated from the adrenal cortex, as well as from oranges and cabbage, a silver-reducing substance, first to be known as hexuronic acid. The suggestion was made by Harris in Cambridge, and by Tillmans and Hirsch in Germany, that this substance might, in fact, be identical with vitamin C. In 1932, when Waugh and King in the United States had at length succeeded in isolating an undoubted specimen of pure, crystalline vitamin C, they reported that it possessed all the properties of hexuronic acid; and almost simultaneously Svirbely and Szent-Györgyi in Hungary confirmed the antiscorbutic potency of hexuronic acid. The identity was not universally accepted at first; but tests soon proved that there was, in fact, an unfailing and quantitative correlation between the presence of hexuronic acid and antiscorbutic potency. Doubts were finally set at rest when the chemical structure was worked out, and the synthetic product was found to have identical activity with the substance isolated from natural sources. The vitamin was then renamed ascorbic acid.

Later advances have included, for example, the development of chemical methods for the estimation of vitamin C; and techniques have been devised for the assessment of vitamin C status in human subjects. Another point of interest is the recognition of the fact that the requirements for the vitamin are increased in infection. Among animal species, primates and guinea pigs are unique in needing vitamin C in their diet; all other animals, so far as is known, synthesize it in their bodies, the precursor apparently being glucose.

During the Second World War, the accumulated scientific knowledge on vitamin C which had so recently been won could be put to good service. Government action was taken to ensure an adequate supply of concentrated orange juice, or of black-currant juice, or synthetic ascorbic acid, for mothers and young children; encouragement was given to the cultivation by householders of fresh fruit and vegetables on 'allotments'; housewives were advised what measures should be taken to minimize losses on cooking; and procedures were worked out for manufacturing dehydrated vegetables, to be used, for example, in the desert campaign, which still retained their vitamin C. No outbreaks of scurvy were seen during the Second World War, in contrast with the conditions referred to above in the First World War, when outbreaks had occurred among the civilians in all the belligerent countries (including Great Britain and the United States), as well as among the armed forces at the various fronts, the total number of cases running into many thousands.

Little is yet known about the detailed physiology of vitamin C action, except that it is needed for the elaboration of the intercellular cementing substance, collagen, or, in a more general way, for the functional activity of the formative cells in general. Chemically, the vitamin is concerned in the conversion in the animal organism of folic acid (pteroylglutamic acid) into folinic acid, and in the metabolism of tyrosine. Vitamin C itself has intense reducing activity, but it has not yet been shown that its characteristic antiscorbutic action can be attributed intrinsically to its redox properties.

Among various new points brought out at the Lind Bicentenary Conference, held in Edinburgh between May 22 and 23, was the suggestive fact, mentioned by C. G. King, that ascorbic acid may also have a role to take in the metabolism of cholesterol. At this meeting, contributions relating to vitamin C and allied topics were made by the following: Surgeon Vice-Admiral Sir Sheldon Dudley ("The Lind Oration"), Sir Edward Mellanby (opening remarks), Dame Harriette Chick ("Early Investigation of Scurvy and the Antiscorbutic Vitamin"), Dr. C. G. King ("The Discovery and Chemistry of Ascorbic Acid"), Dr. M. van Eekelen ("The Occurrence of Vitamin C in Foods"), Prof. H. A. Krebs ("The Sheffield Experiment"), Prof. S. B. Wolbach ("The Histology of Scurvy"), Prof. V. P. Sydenstricker ("The Impact of Vitamin Research on the Practice of Medicine"), Dr. J. H. Crandon ("Ascorbic Acid Deficiency in Human and Experimental Subjects"), Dr. R. M. Kark ("Ascorbic Acid in Relation to Scurvy, A.C.T.H. and Surgery"), Prof. E. J. Bigwood and Dr. J. P. Dustin ("Amino-aciduria in Infancy and Ascorbic Acid Deficiency"), Dr. C. P. Stewart ("Dehydroascorbic Acid in Human Blood Plasma"), Mr. A. J. Lorenz ("Pre-Lind Writers on Scurvy"), Dr. H. Gounelle and Dr. H. Teulon ("Contribution à l'étude de le Vitamine C dans certains états physiologiques et pathologiques chez l'homme"), Dr. W. J. Darby ("The Relationship of Ascorbic Acid to Tyrosine and to Hæmopoietic Vitamins"), Dr. L. W. Mapson and Dr. F. A. Isherwood ("Synthesis of Ascorbic Acid in Plants and Animals"), and Dr. Leslie J. Harris (chairman's summing-up). The proceedings are to be printed in full in a special, forthcoming issue of the *Proceedings of the Nutrition Society*. Obviously, anyone interested in the field of vitamins, whether from the separate aspects of biochemistry, physiology, dietetics or public health, will have need to consult this issue of the *Proceedings*. Together with the reprint of Lind's "Treatise", this record will form a fitting and permanent memorial to the pioneer whose memory was honoured at the bicentenary meeting.

HIGH-FREQUENCY ELECTRICAL MEASUREMENTS

CONFERENCE IN WASHINGTON, D.C.

THE third of the biennial conferences organized jointly by the American Institute of Electrical Engineers, the Institute of Radio Engineers and the National Bureau of Standards was held during January 14–16 in the Auditorium of the Interior Department in Washington, D.C. It was divided into four technical sessions dealing respectively with the measurement of frequency, length and time, power and attenuation, transmission and reception, and impedance. A list of the authors[1] and the briefest abstracts of the twenty-seven papers that were read would occupy the space of this article, and it will perhaps be preferable to select for more detailed treatment those subjects of particular interest to the writer.

Before the first session Dr. A. V. Astin gave a short address of welcome to the seven hundred delegates, and stressed the importance of the conference in helping specialists to keep abreast of this rapidly developing field of work. The chairman of the session, Dr. Harold Lyons, then introduced Dr. L. Essen, who described the frequency standards developed at the National Physical Laboratory, Teddington, their application to microwave measurements and, in particular, to the determination of the velocity of electromagnetic waves and the refractive indices of gases. The experiments involve the accurate measurement of both frequency and wave-length. Extensions of well-known techniques have given an accuracy of frequency measurement, throughout the radio-frequency spectrum, of one part in 10^8, and microwave optics have been developed to give an accuracy of wave-length measurement of one part in 10^6. Dr. Essen made use of a cavity resonator which is the microwave analogue of the Fabry–Pérot interferometer, while K. D. Froome used the analogue of the Michelson interferometer. The final accuracy that can be given for the value of the velocity of light, c, depends on the analysis and elimination of systematic errors due, in one case, to the imperfections of the surface of the resonator and, in the other, to the diffraction of the beam of radio waves at the transmitting horn and reflector. The values obtained are 299,792·5 ± 1·0 km./sec. and 299,792·6 ± 0·7 km./sec.

Dr. K. Bol then gave some previously unpublished details and the final result of the velocity determination initiated by Prof. W. W. Hansen at Stanford University. One of the main experimental difficulties had been the measurement of the length of the resonator, and this is probably mainly responsible for the spread of 2·2 km./sec. in the results. The final result of the measurements was given as 299,789 ± 0·5 km./sec.

In view of the interest in the subject, a special discussion meeting was arranged by Dr. Lyons. The presence of so many of those concerned with the recent determination of the velocity of light would, he thought, afford a good opportunity for discussing the discrepancies between the various results, the question which is still sometimes raised of the variation of the velocity with time or frequency, and the best approach to a number of new measurements which are being planned. The result diverging most from the average of recent values is that obtained by D. H. Rank and his co-workers, from an examination of the infra-red and microwave spectra of hydrogen cyanide. Prof. Rank, although not at the meeting, had said earlier that there is some dissatisfaction with the wave-length measurements and that a new determination now in progress should give a considerably higher accuracy. In view of this and of some criticisms that were made about the way in which the final result is derived from the measurements, there was a general feeling that too much importance should not at present be attached to the discrepancy, although the method is one of great interest and potential importance.

The difference between the two cavity-resonator results was discussed at some length, but was not satisfactorily explained. The technique employed at Stanford does not enable the effect of surface imperfections to be eliminated experimentally as it is in the work at the National Physical Laboratory, but Prof. E. L. Ginzton and Dr. Bol did not think that this effect could be large enough to account for a difference of 3 km./sec.

Commander C. I. Aslakson, who was responsible for the determination of the velocity of light by radar, thought that the precision could possibly be increased if the operators, drawn from the United States Air Force, were able to work on the project for a longer time once they had become skilled in the elaborate technique required to give a reliable result. J. E. R. Ross, of the Canadian Geodetic Survey, said that the average accuracy achieved in the use of radar for the rapid surveying of large tracts of land, the value of the velocity of light being assumed, was 5 parts in 10^5. Dr. Essen expressed the view that if systematic errors had been assessed more carefully, all the results for the velocity would be in agreement within the experimental limits and that there is therefore no evidence to justify speculations concerning the variation of velocity with either time or frequency. The probable error of the work at the National Physical Laboratory is ± 1 km./sec., and further work now in progress is likely to reduce it to ± 0·3 km./sec. Any future work designed to improve our knowledge of the velocity of light should therefore aim at an accuracy of at least 0·3 km./sec.

The work on velocity afforded an interesting application of cavity resonators. The two following papers were concerned with their more general properties, G. L. Hall describing the analysis and measurement of their circuit parameters and A. E. Wilson the techniques adopted at the National Bureau of Standards, Washington, D.C., for their rapid and accurate calibration as wavemeters.

The remaining part of the session was occupied by three papers dealing with frequency standards and measurement. T. A. Pendleton described an investigation at the National Bureau of Standards on the use of quartz standards as resonators. Their frequencies were measured daily, and it was hoped that the drift would be less than that of similar quartz units maintained in continuous vibration. To secure constant operating conditions, some of the resonators were housed at the bottom of 60-ft. shafts where the temperature was stable to about ±0·001 deg. C. A. S. Bagley gave details of a new equipment for the measurement of frequency and time interval which was based on the use of counting-circuits operating at a rate up to 10^7/sec.; and finally W. E. Leavitt described an electronic chronograph readable to 0·02 msec. A further paper on frequency measurement was read at the last session. In this H. J. Finden gave an account of the extension of frequency synthesis and the production in a decade scale of standard frequencies up to 100 Mc./s. in steps of 1 kc./s.

At the next session, presided over by E. W. Houghton, there were three papers on power measurement and three on attenuation. In the first, M. S. Tanenbaum, dealing with the power that waveguide components can withstand without discharge breakdown, pointed out the need to express results on a statistical basis and suggested that the criterion of breakdown power should be that causing breakdown on 50 per cent of its applications. One of the difficulties of the tests at very high frequencies is the generation of the necessary power or voltage, and three ways of overcoming this have been used: a standing wave is produced in the guide to give voltage magnification; the dimensions in one direction of the guide are reduced; or the pressure is reduced by a known amount. From the results, the behaviour for normal conditions in the guide can be calculated. The lively discussion following this paper was evidence of the wide interest in breakdown problems. H. H. Grimm followed with a description of some pressurized, broad-band, water terminations used as calorimeters and concluded that the hairpin type, modified in order to reduce reflexions, gives the best performance, having a voltage standing-wave ratio of less than 1·03 for a power-level of 1·5 kW. and over a 5 per cent range of frequency. R. W. Lange explained some of the difficulties associated with bead thermistor power-meters. An instrument has been developed for 10 kMc./s. having full-scale sensitivities of from 4,000–40 μW. To achieve the accuracy required, it is necessary to select pairs of thermistors having not only the same characteristics but also similar ageing tendencies.

Attenuation measurements are based on the use of standard cut-off attenuators, and the precisely made microwave instrument described by R. W. Hedberg represents a useful contribution in this field. It employs the TE_{01} mode in a rectangular guide, and the effects of mode purity and mode filtering were fully discussed. A resistance card attenuator of novel form was described by B. P. Hand. The card is oriented in the waveguide at a variable angle with respect to the plane of polarization and gives an attenuation range of from less than 1 db. to 50 db. It is suitable for high frequencies at which cut-off attenuators are impracticable without frequency correction.

Most of the papers read at the conference were short accounts of original work, and two demonstration lectures given between the second and third sessions allowed the delegates a little mental relaxation. In the first, A. G. Fox showed how, in the millimetre wave-length range, dielectric waveguides can be used for flexible patchcords and other circuit components. He then gave a simplified explanation of Faraday rotation in a ferrite medium, using a most ingenious model of a spinning electron. A uniform magnetic field was simulated to produce precession, and a rotating magnetic field to produce a change in the angle of this precession. In the second lecture R. L. Wallace demonstrated some of the properties of a new high-frequency transistor. It enables instruments such as lapel microphones and hearing-aids to be made very small in size, and the total bulk of the batteries required to operate them for a period of a year was shown to be only a small fraction of that required by present-day instruments. The audience was left in no doubt about the importance which the new transistor will have when it becomes generally available.

A basic requirement in all high-frequency measurement work is the provision of suitable sources of oscillation, and three papers read at the session on transmission and reception, at which J. W. Kearney was the chairman, were concerned with this problem. N. A. Spencer described a waveguide cavity designed for the external tuning of the *RK*-5721 reflex oscillator tube. The mechanical tuning by means of non-contact plungers and the voltage adjustments are operated by a single control, and a range of approximately 8–10 kMc./s. is obtained with a power output of approximately 50 mW. S. F. Kaisel gave details of a new type of oscillator, which can be tuned, by varying the voltages on the electrodes, over a frequency range of more than one octave. He also gave a survey of the frequency-ranges and power-levels obtained at various laboratories. In the millimetre region the difficulties of generation become very much greater, and quite new principles may have to be employed. There was no paper at the conference dealing with such investigations, but C. W. Johnson showed what can be done with existing equipment. An oscillator in the region of 24,000 Mc./s. (1·25 cm.) is fed to a crystal diode, and by careful adjustment of the circuits a usable amount of power at harmonic frequencies up to the tenth can be obtained. The cartridge of the crystal diode, of type 1N31 for example, is slotted near the crystal and is then fitted in a waveguide assembly so that the slot is across the small guide, in which the harmonics are generated. In an alternative form the diode is dismantled, and the crystal and cat's-whisker are connected directly across the waveguide carrying the fundamental frequency. The power obtained at 100 kMc./s. (3 mm.) is 10 μW., which is adequate for many purposes.

Later in the session C. F. Edwards gave an account of some tests on microwave noise-generators, which indicate that, after an initial ageing period, the microwave noise-output of a fluorescent lamp is remarkably constant; for example, a lamp with a relative noise output of 15·75 db. changed by 0·5 db. in the first few hours, after which no further change was detectable.

F. J. Gaffney presided over the last session, at which a wide range of impedance-measuring equipment was described. In many instances a rapid inspection of the matching of a transmission system is required rather than an actual measurement of impedance, and a very useful equipment for such purposes was described by W. P. Peyser. The frequency range covered by two instruments is 100–1,350 Mc./s., and an oscilloscopic presentation of the variation of voltage standing-wave ratio with frequency is provided so that adjustments to the component under test can be made to give the best performance over the required range. A relatively inexpensive slotted line for the measurement of impedance and standing-wave ratios was described by C. F. Miller. The line is approximately three metres long, the central conductor being supported by a thick-walled 'Styrafoam' cylinder. Some of the problems encountered in the conversion from balanced to unbalanced systems were considered by O. M. Woodward, jun., and a device for measuring the efficiency of the transformers used was described.

For the comparison and measurement of impedance in the microwave region, bridge methods using hybrid junctions are likely to be increasingly important, and M. D. Adcock's description of a new type of junction was therefore particularly interesting. The symmetrical arms of a conventional junction, or magic *T*, are arranged to be contiguous and parallel to the *H*-plane arm. A voltage standing-wave ratio of less than 1·1 for all arms is obtained with an isolation greater than 50 db. between the *E*- and *H*-plane arms. These figures hold for a frequency-range of 12 per cent, and the method of construction makes the power-handling capacity of the junction as high as that of the corresponding waveguide. In another interesting paper G. Deschamps showed how impedance measurements can be made on non-conventional guides such as microstrip by using standard equipment and correcting for the junction discontinuity.

In addition to the technical sessions, visits were arranged to the National Bureau of Standards, the U.S. Naval Observatory, the Naval Ordnance Laboratory and the Naval Research Laboratory; and a luncheon was held at the Hotel Statler. The guest speaker at the luncheon, Dr. A. T. Waterman, gave an interesting account of the work of the National Science Foundation and expressed some concern that, under present conditions, it has been necessary to allocate a considerable proportion of the funds of the Foundation to applied science instead of to fundamental research.

The keenness of the delegates, the strict adherence to the time-table and the smooth working of the organizational arrangements were features of this successful conference, and were evidence of the preparatory work of the joint committee under the chairmanship of Mr. E. P. Felch. It is, incidentally, a pleasure to record that the committee acted as most hospitable hosts to the overseas delegates.

This article is published by permission of the Director of the National Physical Laboratory.

SOUNDS OF JETS

By Dr. E. G. RICHARDSON

King's College (University of Durham), Newcastle upon Tyne

THE vibration of jets of water or gas issuing into the atmosphere has been a favourite study in classical physics for more than a century. Plateau was one of the early students of this phenomenon, and in his treatise, "Theory of the Modifications experienced by Jets of Liquid issuing from Circular Orifices when exposed to the Influence of Vibratory Motions", he showed that a column of liquid subject to surface tension undergoes rhythmic changes of figure of the type named by Lord Rayleigh as 'varicose'. Later, it was shown that the jet under vibration could also pendulate from side to side, both types of oscillation eventually causing the jet to break up into drops. A kindred study of the early days was that of the sensitive flame, a favourite topic of Royal Institution Discourses given by Tyndall. Shorn of the unessential combustion, this comprises a jet issuing from a narrow orifice without capillarity forces—that is, of a liquid into liquid or of a gas into gas—which, though inherently unstable, could have its instability rhythmically controlled by a sound.

None of these jets however, except some varicose water jets, has any preferred frequency. For this, some form of resonance or interference is necessary. The earliest form that this took was to let an air jet impinge on a sharp wedge. Such 'edge tones' were first heard by Sondhauss; and later Wachsmuth, noticing the relationship between this phenomenon and the diapason organ pipe, took photographs of the jet, to which ether vapour had been added. He showed that, if the distance from slit to edge is kept constant, and air at low pressure admitted to the wind chest behind the slit, the pitch of the edge tone rises with efflux velocity (with some jumps of frequency at certain pressures), while if the wind pressure is kept constant and the wedge moved away

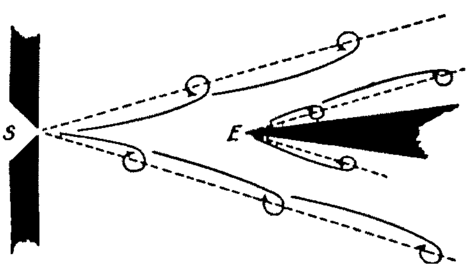

Fig. 1

from the slit, an opposite effect on the pitch occurs. When the well-known alternate vortex street behind an obstacle in a stream was set on a theoretical basis by von Kármán, a similar vortex system was invoked to explain what could be seen in an edge-tone jet, although it was recognized that the eddies do not emerge full-grown from the slit but gather strength as they are carried towards the edge.

About twenty years ago, two rival theories of the edge tone were current. One regarded the phenomenon as purely acoustic; each time a vortex hit the edge a sound wave signalled back to the edge to start another one. E. G. Richardson[1] thought that he had disposed of this theory by opening another jet alongside the principal one and showing that the postulated sound wave is unable to set this subsidiary jet into pendulation; but recently A. Powell[2] has revived this hypothesis. The second theory was a hydrodynamic one, based on an observation of Richardson that a secondary vortex system is set up in the boundary layer alongside the wedge, as shown in Fig. 1, and that these have to fall into line with the main system to form two vortex streets, one each side of the wedge. N. Curle[3] has recently taken up and extended this theory, showing that the hydrodynamic reaction on the fluid debouching from the slit results from the alternating transverse velocity at the tip, without the intervention of any sound signal. At low velocities, when the edge tone results from a simple periodic pendulation, it ought surely to be possible to give a purely hydrodynamic explanation to the phenomenon. It may be noted, indeed, that pendulations similar to those of edge tones may be produced when underwater jets strike an opposing wedge at speeds far too low to engender sound waves in the water[4].

Reverting to the unassisted jet (from a circular orifice), one may assume that the origin of the hissing noise which accompanies the efflux of air at moderate speeds is to be found in shearing forces, both within the nozzle and outside where a 'surface of discontinuity'—as Helmholtz called it—exists between the fast-moving and the more-or-less stationary air. Here boundary layers engendering turbulence are to be found, at first apparent as small eddies or high-frequency fluctuations; but farther down the jet these roll up into larger ones, involving fluctuations of lower frequency. Examination of the spectrum of turbulence with hot wires and of the associated sound spectrum with microphones show them to be closely parallel. (This has recently been shown in jets[5], but was earlier demonstrated in wind tunnels[6] and with respect to the sounds of natural turbulence in the open air[7].) At any rate, confirmation of the statement about the relative sizes of the jet eddies can be found when one traces back the sound picked-up from the microphone to its origins, the high-frequency sources then being revealed as located near the nozzle, while the low-frequency sources are to be found farther downstream and carried with the jet.

It is a matter of more than theoretical interest to determine what kind of sources are involved in jet systems, since this determines how and in what particular directions the sound will be radiated into the neighbourhood. W. L. Nyborg *et al.*[8] discovered maxima of intensity in directions at right-angles to the axis of a linear jet – edge system with minima in line of the jet, both behind and before. Thus, the polar curve corresponds to an acoustic dipole source ($p = p_0 \cos\theta$). At higher speeds the maxima for a circular jet (without edge) lie at 45° to the axis, corresponding to a set of acoustic quadrupoles. This is the basis of M. J. Lighthill's[9] theory for the (subsonic) jet in which he obtains an expression for the quadrupole field in terms of the second differential of the stress tensor ρuv (where ρ is the density, u and v the component velocity fluctuations in perpendicular directions). This stress is also the basis of Reynolds's theory of turbulence and is known by his name. Having localized the sound intensity at places of large shearing forces, Lighthill then proceeds to map out the sound field and also to prove that the overall sound intensity will be proportional to the eighth power of the efflux velocity, showing how important this factor is for the production of noise.

These conclusions are fairly well supported by experiments on model jets. Such 'smoothing' of the polar curves for intensity in comparison with theory as is observed can probably be ascribed to the scattering of the sound as it passes through the turbulent field[7].

When the speed of efflux from the nozzle exceeds that of sound in the gas, a change in the disposition of the jet ensues. Schlieren photographs show that the jet alternately expands and contracts, while it is criss-crossed with a system of shock waves originating at the nozzle and reflected at the confines of the jet. The phenomenon is now acoustic rather than hydrodynamic in mechanism. One can, for example, let the jet—from a circular nozzle—impinge on a coaxial metal ring to produce edge tones of a definite frequency, but only if one places the round edge near one of the zones of instability at which the shock waves are reflected (Fig. 2). Presumably in this case there is resonance of the waves reflected from the ring with those set up at the nozzle, as suggested by Wachsmuth for the low-speed edge tone. The jet – edge system just described is, in fact, the basis of the Hartmann generator[10] in which, by constructing the apparatus on a miniature scale (nozzle about 0·5 mm. diameter, jet-edge separation about 1 mm.), this investigator was able to construct a source of ultrasonic frequency.

A jet of supersonic velocity is, in fact, an efficient converter of momentum into acoustic power, some of it audible, some ultrasonic. It has been suggested by E. J. Richards[11] that the origin of this excess noise (above that of a merely turbulent jet) arises from the interaction of the shock waves with the turbulent boundary layer or 'surface of discontinuity'. On this idea the zones of instability aforesaid will

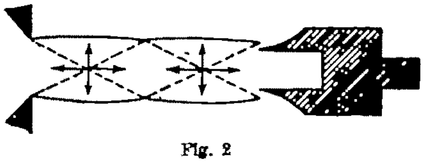

Fig. 2

become potent sources of sound. The sound field around the jet will then be rather like that of light in front of an optical grating—that is to say, there will be directions in which the energy from different sources will constructively and destructively interfere—and there is some experimental evidence, from polar curves of supersonic jets, which supports this. What is perhaps more important is that in this range of speeds the noise-level increases at a power of the jet velocity much higher than the eighth—perhaps, the twentieth or more.

This behaviour of jets at subsonic and supersonic speeds was described by Prof. E. J. Richards and G. M. Lilley at a symposium on "Aeronautical Acoustics, in particular Jet Noise", held in London on May 21 under the joint auspices of the Royal Aeronautical Society and the Acoustics Group of the Physical Society. Other speakers dealt with the noise of jets in gas-turbine engines (F. B. Greatrex) and the noise of jet aircraft (N. Fleming and J. D. Hayhurst). The bangs heard as an aircraft crosses the sound barrier were described by C. H. E. Warren, and these have been the subject of a recent article in *Nature*[12].

In the discussion which followed, speakers emphasized the nuisance which the starting and landing of aircraft constitute to those who live and work in the vicinity of aerodromes and the need for mitigation of the noise if aircraft travel at still higher speeds. Some of the speakers described tests of devices to reduce jet noise, but none of the reductions amounted to much in terms of decibels. A dilemma seems to have been reached in which the only cure for the noise is to reduce efflux velocity, but this means wider jets to maintain the thrust and so heavier engines, which could rob the gas turbine of one of its chief advantages.

OBITUARIES

Sir Robert Archibald, C.M.G.

Robert George Archibald died suddenly on May 2 in Salisbury, Southern Rhodesia, at the age of seventy-three years. He was the son of the Rev. W. F. Archibald, chaplain to the Forces, and was educated at Dollar Academy and the University of Edinburgh, where he graduated in medicine in 1902. After holding various house appointments, he entered the Royal Army Medical Corps in 1906, and was a pathology prizeman in the Royal Army Medical College, where he worked with Sir William Leishman. In 1907 he was seconded to the Sleeping Sickness Commission in Uganda. In 1908 he was attached to the Egyptian Army and appointed assistant pathologist and bacteriologist in the Wellcome Tropical Research Laboratories, Khartoum, which was then a department of Gordon Memorial College. Here he was destined to spend the next twenty-eight years, years of memorable service during which the Wellcome Laboratories in Khartoum became world-famous as an institute of tropical research under the direction of Sir Andrew Balfour, later of Dr. A. J. Chalmers, and finally of Sir Robert Archibald himself. He held the post of director from 1920 until his retirement in 1936, when the Wellcome Tropical Research Laboratories were divided among various departments of the Sudan Government.

These were years of intense productive activity. Archibald contributed numerous papers to the Reports of the Wellcome Tropical Research Laboratories, and with Balfour he compiled the "Reviews of Recent Advances in Tropical Medicine", published as supplements to the Reports and continued as the *Tropical Diseases Bulletin* by the Bureau of Hygiene and Tropical Medicine in London. He was a contributor to the "Oxford Index of Therapeutics" (1921) and editor (with Byam) of the monumental treatise, in three volumes, on "The Practice of Medicine in the Tropics" (Oxford Medical Publications). Archibald's own researches during this period are scattered through the scientific and medical journals in innumerable articles covering almost every aspect of tropical medicine and hygiene. He was local secretary of the Royal Society of Tropical Medicine and Hygiene, president of the Sudan Branch of the British Medical Association, member of the executive committee of the British Empire Leprosy Relief Association and *membre correspondant* of the Société de Pathologie Exotique. He was one of the original members of the Council of the Kitchener School of Medicine and later a member of its executive committee in London. He was also a member of the executive committee of the University College of Khartoum.

During the period of his Sudan service, Sir Robert Archibald saw active service in the Blue Nile operations (1908), Mediterranean Expeditionary Force (Dardanelles, 1915), and in the Darfur expedition (1916). He was several times mentioned in despatches; he was awarded the D.S.O. in 1917, C.M.G. in 1928 and created knight bachelor in 1934. He was awarded also the Order of the Nile (second class) and Order of the Mejidieh (fourth class). After his retirement from the Sudan, Sir Robert Archibald was for a time medical superintendent of the Chacachacare Leper Settlement, Trinidad, West Indies. Later, during the Second World War, he was pathologist, County Laboratory, Poole, Dorset, and for some years before his death he was professor of bacteriology and parasitology in the Farouk University, Alexandria, Egypt.

Although it is nearly twenty years since Sir Robert Archibald left the Sudan, he is still remembered here with deep affection and respect—the good physician, able investigator, wise administrator, kind teacher and great gentleman whose death symbolizes the passing of an era. Robert Kirk

Prof. D. Hanson

Prof. Daniel Hanson was born in 1892 and was educated at Wallasey Grammar School and at the University of Liverpool, where he took the degree of M.Sc. After a short time at the Research Department, Woolwich, he went in 1913 to the National Physical Laboratory as junior assistant (now called junior scientific officer) in the Metallurgy Division.

In 1914 the superintendent of the Division, Dr. W. Rosenhain, went on a world lecture tour, and while he was away the First World War broke out. The two senior members of the staff were called to the colours, and Hanson and one other were left to carry on the metallurgical side of the work.

Hanson rose to be senior scientific officer in the Department, and published some twenty-five to thirty papers, mainly on aluminium alloys, impurities in copper, and fatigue in metals. His early interest was in constitutional diagram work, as exemplified by the excellent series of papers which he published with Marie L. V. Gayler on various binary and ternary aluminium alloys, work which set a new standard of accuracy at that time and which has rarely, if ever, been surpassed since. While it is obvious that his interests covered a much wider field as time went on, the accurate determination of an equilibrium diagram was always a subject that attracted his attention.

In 1926 Hanson left the Laboratory to take up the post of professor of metallurgy in the University of Birmingham—a position which he held until his death on June 12. The department, which was quite small when he took it over, grew until in the last few years he was director of a department that had three professors besides himself in addition to a number of lecturers and research students. The buildings also were considerably enlarged, a special block being erected for the Industrial Metallurgy Section, and an extra floor being added to the main building.

The subjects which he had studied at the National Physical Laboratory still claimed Prof. Hanson's attention, but he added to them cast iron and tin alloys. In all he published about seventy papers in the *Journal of the Institute of Metals*, the *Journal of the Iron and Steel Institute*, and various other places.

Hanson established a reputation for himself, not only in Great Britain but also in many other parts of the world. He lectured in Australia, Canada, New Zealand, the United States and elsewhere. In particular, he gave the Institute of Metals Autumn Lecture in 1930, a British Exchange Paper at the International Foundry Convention meeting in Paris in 1932, and the eighteenth annual lecture to the American Institution of Mining and Metallurgy at its New York meeting in 1949. He also was a member of the delegation of British scientists that discussed, in 1950, the release of information on atomic research with American and Canadian scientists. He served for many years on the Council of the Institute of Metals, and was a vice-president from 1928 until 1939.

In spite of all his success in his professional life, Hanson had a complete absence of 'side'. He had very great charm and will be much missed by a large circle of friends. J. L. HAUGHTON

NEWS and VIEWS

H. A. Lorentz (1853–1928)

A GREAT architect of the new era in physics and one of the most cosmopolitan men of science of all times, Hendrick Antoon Lorentz was born at Arnhem in Holland a century ago on July 18, 1853. He studied at the University of Leyden, where he graduated in philosophy in 1875, and became professor of theoretical physics at the early age of twenty-four. He was a voluminous writer, and his publications appeared in rapid succession over a period of more than fifty years in Dutch, French, English and German periodicals. His paper, "La théorie électromagnétique de Maxwell et son application aux corps mouvants" (1892), introduced and vindicated the conception of the electron in physics and supplemented Maxwell's theory on electromagnetic phenomena. His electronic theory of matter harmonized completely with the view which followed from J. J. Thomson's researches. Lorentz's expectation that a magnetic field would affect the appearance of spectra was realized in 1896 by his pupil, Pieter Zeeman, with whom he shared the Nobel Prize for Physics in 1902. The introduction of Lorentz's transformation revolutionized theoretical physics and became the foundation stone for the theory of relativity of another pupil of his, Albert Einstein. As early as 1880 he demonstrated the respective relations existing between the refraction of light and the density or aggregate condition, gaseous or fluid, of a translucent body. These relations were recognized independently and on different grounds by the Danish physicist, L. V. Lorenz, and are known to-day as the Lorentz–Lorenz relations. In Britain, Lord Rayleigh and Sir Oliver Lodge were chiefly responsible for making known Lorentz's work. Lorentz retired from the University chair in 1912, when he was appointed director of the Teyler Laboratory at Haarlem, and he died suddenly on February 4, 1928, at the age of seventy-four. Innumerable honours were showered on this simple, modest and likeable man, and, among British honours, he was elected a Foreign Member of the Royal Society in 1905 and received its Rumford Medal in 1908 and the Copley Medal in 1918. Besides his purely scientific work, Lorentz excelled at international gatherings, where his idiomatic command of languages and great personal charm won the respect and affection of men from all countries.

Royal Society of Edinburgh: Honorary Members

THE following have been elected Honorary Fellows of the Royal Society of Edinburgh: *British:* Prof. Sydney Chapman, Department of Natural Philosophy, University of Oxford; Prof. A. C. Chibnall, lately Sir William Dunn professor of biochemistry, University of Cambridge; Dr. A. T. Doodson, director of the Liverpool Observatory and Tidal Institute, Birkenhead; Sir Harold Jeffreys, Plumian professor of astronomy, University of Cambridge. *Foreign:* Prof. C. P. H. Dam, Department of Biochemistry, Polytechnic Institute, Copenhagen; Dr. G. Egloff, director of research, Universal Oil Products Co., Chicago; Prof. K. M. G. Siegbahn, of Stockholm; Prof. O. Struve, Department of Astronomy, University of California.

Funds for Colonial Welfare and Development

IN reply to a question in the House of Commons on June 24, the Secretary of State for the Colonies said that he hoped it would be possible to introduce legislation to provide further funds for Colonial development early in the 1954–55 session. Meanwhile, Colonial Governments could proceed on the assumption that the period in which the £140 million provided under the Colonial Development and Welfare Acts of 1945 and 1950 may be spent would be extended beyond March 31, 1956. Colonial Governments were also being informed that, where necessary for essential development, they may enter into commitments extending beyond 1956 and exceeding the £140 million already provided, up to a limit of £7 million, and subject to Treasury concurrence, on the understanding that in due course Parliament would be asked to vote the necessary moneys. Mr. Lyttelton also said that because of the serious world rice shortage, funds had been made available to a maximum of £3 million for promoting the production of rice in the Colonies. The special schemes for growing rice might ultimately involve expenditure exceeding the statutory limit, and such expenditure would be covered by the legislation already indicated.

Commonwealth Bureau of Pastures and Field Crops

The Commonwealth Bureau of Pastures and Field Crops, which has been attached to the Welsh Plant Breeding Station, Aberystwyth, for the past twenty-four years, will be transferred to Hurley, Berkshire, in August, where it will be attached to the new Grassland Research Station, of which Dr. Wm. Davies is director. This Bureau, one of the ten Commonwealth Agricultural Bureaux, was founded at Aberystwyth in 1929, its first consultant director being Prof. (now Sir) George Stapledon. For the first twenty years of its existence the Bureau was in charge of Dr. R. O. Whyte, who was succeeded as director in 1949 by Mr. A. G. G. Hill, formerly director of the East African Agricultural Research Institute, Amani. The Bureau issues the quarterly abstract journals *Herbage Abstracts* and *Field Crop Abstracts*, in addition to its other activities.

Conditions in the Rajputana Desert

A number of Indian authorities took part at New Delhi in a symposium on the Rajputana Desert, called formerly the Great Indian Desert. The lengthy papers have now been published in full (*Bull. Nat. Inst. Sci. of India*, No. 1, Sept. 1952). These are prefaced by a general review by the president, Dr. S. Lal Hora. The economic problem that gives this region great interest is the report that the desert is rapidly spreading and, furthermore, that the desert conditions are becoming intensified. These conditions may be due, if they do occur, to at least three causes: first, change of climate; second, drifting of sand to adjoining districts; and third, overgrazing on the confines, deforestation and wasteful methods of cultivation. The extent of the creep of desert conditions north and north-east has been estimated at more than half a mile a year, but this occurrence is not universally accepted, for it must be remembered that the Rajputana Desert is not a true hot and arid desert, since part of it gets enough rain to afford pasture at certain times. The atmospheric conditions are discussed in full in this monograph. Former better watered conditions are undeniable, as old water-courses and archæological remains show. One means of checking deterioration is to limit grazing on the edge and reafforestation so far as possible. A limited amount of grazing and cultivation is certainly possible in some parts and might be increased in good years, but decreased in dry conditions.

Marine Biology in the Irish Sea

Most zoologists will welcome the fifty-eighth volume of the *Proceedings and Transactions of the Liverpool Biological Society* (vol. 58; pp. vi+109; 25*s*.). Over a long period of time under a changing editorship (the latest editors are Mr. J. S. Colman and Dr. J. W. Jones) this well-known series has published many notable contributions to marine biology. The present volume contains three papers which together add appreciably to our knowledge of the natural history of the Irish Sea. The first paper, by Dr. D. I. Williamson, describes the distribution in the Irish Sea of some important plankton species in relation to water movements. A point that emerges in comparison with earlier work is the stability, during the present century, of the composition of the plankton in the central Irish Sea. This contrasts markedly with the changes which have taken place in the plankton of the western English Channel during the same period. Dr. Williamson concludes that the Irish Sea plankton is less dependent on influxes of oceanic water than is that of other areas, and suggests that local regeneration in a relatively deep and stable water-mass overlying a muddy bottom helps to support the rich zooplankton characteristic of the area. The second paper, by Mr. A. B. Bowers, is concerned with the spawning grounds and the larval stages of herring in the same region. Manx herring spawn, in autumn, on rough ground a few miles east of the Isle of Man where two water-masses mix. One of these water-masses contains a *Sagitta elegans* community, the other a plankton characterized by *S. setosa*. The growth-rate of the Manx autumn-spawned herring is considerably less than that of spring-spawned herring in the Clyde. The final paper, by Dr. Sheila S. Meredith, is a study of the common shrimp, *Crangon vulgaris*, in the Dee estuary and in Morecambe Bay. Large quantities of this crustacean are caught annually for human consumption, but until recent years its biology has not been intensively examined. It is useful to have this account for comparison with similar recent work in the Severn estuary.

Variation in the Lesser Celandine

In Great Britain, diploid and tetraploid races of *Ranunculus ficaria* often occur in the same population, the former being fertile, the latter highly sterile and multiplying largely by bulbils in the leaf axils. In Sweden it is the tetraploid—probably an autotetraploid—form of the species that is widely distributed, according to A. M. Perje (*Arkiv. för Botanik*, Stockholm, **2**, Pt. 1–3, 251, 1952). This investigator has found that abnormalities occur in the formation of the pollen grains, though some fertile pollen is always produced. The embryo-sacs are normal up to the eight-nuclear stage, after which they usually begin to degenerate—a phenomenon which may be due either to heredity or to environment, or to a combination of both. Different clones show marked differences in the numbers of the several floral organs, an increase in stamen number being usually accompanied by an increase in the number of carpels. The observed variability is considered in terms of contemporary genetical theory.

Information Theory

Information theory has a pretentious name, and has received a publicity almost comparable with that of relativity theory in the early twenties. Many scientists who have no time to read the original papers and books by Shannon, by Norbert Wiener and by others, which make rather difficult reading for the non-mathematician, must have the uneasy feeling that they are missing something important. They will be much relieved if they read a short paper by Dr. P. M. Woodward, in the May issue of the *British Journal of Applied Physics*. There they will find that, so far as the non-specialist is concerned, the subject is one the essentials of which can be lucidly and comprehensively dealt with in a few pages. The paper will interest a very wide range of readers.

Postgraduate Engineering Production Courses in the University of Birmingham

A NOTE on developments in engineering production and management studies, contributed by Prof. T. U. Matthew to the *University of Birmingham Gazette* (5, No. 4; 1953), refers to the increasing tendency of graduates in engineering to return to the University after four or five years in industry; and the Birmingham postgraduate diploma course of studies in the principles of engineering production management has been designed to meet the needs of such men who wish to fit themselves for the task of devising and introducing improved products and manufacturing methods, and for subsequent executive posts in production development or administration. During the past four years, fifty graduates have taken this course, and the current group of seventeen graduates includes five from overseas. The Department has also conducted short residential summer schools at Primrose Hill which have been attended during the past four years by more than a hundred and fifty senior managers and production engineers. The Department now plans to provide throughout the year a continuing series of short residential courses of the same nature, and the firm of Joseph Lucas, Ltd., has provided £57,400 for the purchase and equipment of a large house for use as a residential centre. Prof. Matthew believes that the University can play an important part in modern industrial society by providing educational courses and research facilities which bear directly on the problems of increasing industrial productivity and of strengthening the national economy. The major aim of the Department is to carry out scientific investigation on the main lines of study in the graduate courses, and this will be realized more fully when accommodation in the engineering buildings at Edgbaston becomes available next year. Meanwhile, grants from the Department of Scientific and Industrial Research and the Tube Investments Research Fellowship have greatly assisted research on work measurement and job evaluation, the variations in human muscular force, the output variation in repetitive tasks, the nature and acquisition of industrial skills, and the organization and use of scientific and technical information in Midland industries.

International Commission on Illumination (C.I.E.): Meeting of Technical Committee on Daylight

AT the sessional conference of the International Commission on Illumination (C.I.E.) at Stockholm in 1951, it was agreed to hold a special meeting of the Technical Committee on Daylight in 1953 to discuss developments in the subject which were incomplete at the time. This meeting was held, during May 6–9, 1953, at the Abbaye de Royaumont, Creil, near Paris. Delegates from seven countries attended. The arrangements for the meeting were undertaken, on behalf of Australia which was unable to send a delegate, by the British delegation. Papers were presented describing recent work on the distribution of sky brightness, inter-reflexion of light in rooms, total solar radiation, and the systematic control of reflected sunlight in relation to building design in sunny climates. New instruments for the measurement of daylight factor, for the calculation of total daylight factor in rooms, and for the study of nebulosity were shown. An interesting feature of the conference was the apparently closer co-operation between physicist and architect in Britain, Australia and the United States than on the Continent. From the Continent come ingenuity and precision in the study of natural lighting, while the former countries are concentrating on practical applications of the work to building design and the development of simple tools and instruments for the wider use of architects and lighting engineers. The C.I.E. meeting was preceded by a conference organized by the Association Française des Eclairagistes, at which were read summaries of recent work in France, Britain, Sweden and Germany prepared by M. Jean Dourgnon, Dr. R. G. Hopkinson, Mr. Gunnar Pleijel and Prof. W. Arndt, respectively.

Conference on Nuclear Physics

A CONFERENCE on nuclear physics is to be held in the University of Birmingham during July 13–18. Among the subjects to which sessions will be devoted are: low energy-levels and light nuclei; dense energy-levels and the statistical approach; study of the nucleus by high-energy processes; scattering of gamma-rays, angular correlations and conversion coefficients and oriented nuclei and polarized beams; experimental methods; and meson theory of nuclear forces. It is hoped to produce shortly after the Conference a set of notes, summarizing the discussions. About a hundred visitors from overseas and a similar number from universities in Great Britain are expected to be present.

Salters' Institute of Industrial Chemistry: Awards

ON the recommendation of the director, Sir Alfred Egerton, the Court of the Salters' Company has elected the following to be Salters' Fellows for the year 1953–54: W. A. Holmes-Walker; P. P. Manning. Mr. Holmes-Walker has been demonstrator and assistant lecturer in chemistry in Queen's University, Belfast, and has carried out research on the electric and magnetic properties of alkyl-organic compounds; he proposes to carry out research in the Department of Chemical Engineering at the Imperial College of Science and Technology, London, on high-pressure techniques. Mr. Manning (Emmanuel College, Cambridge) has been carrying out research at Cambridge on the theory of molecular structure; he proposes to carry out research in experimental physical chemistry before entering chemical industry as a physical chemist. The Court of the Salters' Company has also elected the following to be Salters' Scholars for the year 1953–54: G. Hetherington, J. P. Howard, P. Kendrick, C. C. McCain and W. L. Wilkinson.

British Memorial Fellowships, Victoria, Australia

BRITISH MEMORIAL FUND FELLOWSHIPS of the State of Victoria, Australia, have been awarded for 1953, as follows: *Agriculture*, Miss Mary D. Thomas (University of Wales); *Virology*, N. P. L. Wildy (Gonville and Caius College, Cambridge); *Natural Science*, Dr. Madeline C. Walters (University of

Birmingham); *Industrial Research*, R. M. McCleery (Magdalene College, Cambridge). Four other Fellowships in metallurgy, pre-school education and child development, arbitration (industrial), and British Commonwealth Studies, respectively, will be awarded next year. All the Fellowships, which are worth £A1,000, are for British subjects, less than thirty-five years old, with at least ten years of residence in the United Kingdom, and are designed to cover travel expenses to and from Melbourne and a stay of ten months in Victoria, commencing at the start of the academic year in March. Further details can be obtained from the Hon. Sir John Lienhop, Victoria House, Melbourne Place, Strand, London, W.C.2.

Society for General Microbiology: Officers

The following have been appointed officers and committee of the Society for General Microbiology for the year 1953–54: *President*, Mr. H. J. Bunker; *Treasurer*, Dr. R. Lovell; *Meetings Secretary*, Dr. E. F. Gale; *General Secretary*, Dr. J. G. Davis; *Editors*, Prof. B. C. J. G. Knight and Mr. A. F. B. Standfast; *Committee*, Dr. P. W. Brian, Prof. W. Brown, Prof. K. E. Cooper, Dr. F. Fulton, Dr. Lillian Hawker, Dr. Betty Hobbs, Prof. J. W. Howie, Prof. J. W. McLeod, Dr. A. A. Miles, Mr. N. W. Pirie, Mr. H. Proom, Mr. G. Sykes, Dr. W. E. van Heyningen and Dr. R. E. O. Williams.

University of London Appointments

The following appointments in the University of London have been announced: Dr. R. A. Shooter, senior lecturer in bacteriology in St. Bartholomew's Hospital Medical College, to the University readership in bacteriology tenable at that College. The title of professor of organic chemistry in the University has been conferred on Dr. D. H. R. Barton in respect of the post held by him at Birkbeck College, and that of reader in chemistry in the University on Dr. Allan Maccoll, in respect of the post held by him at University College.

Colonial Service: Recent Appointments

The following appointments have recently been made in the Colonial Service: P. A. Gething (agricultural officer, Federation of Malaya), senior agricultural officer, Federation of Malaya; A. P. S. Forbes (senior agricultural officer, Nyasaland), M. F. H. Selby (agricultural officer, Nyasaland), R. Smith (senior agricultural officer, Nyasaland) and H. V. T. Webb (agricultural officer, Nyasaland), chief agricultural officers, Nyasaland; J. H. Mackay (senior assistant conservator of forests, Nigeria), conservator of forests, Northern Rhodesia, Nigeria; A. C. Russell (senior assistant conservator of forests, Gold Coast), conservator of forests, Gold Coast; A. Huddlestone (senior geologist, Gold Coast), deputy director, Geological Survey Department, Gold Coast; H. Service (deputy director of the Geological Survey, Federation of Malaya), director of the Geological Survey, Federation of Malaya; A. H. Milne (veterinary officer, Tanganyika), chief veterinary research officer, Tanganyika; J. B. Randall (deputy director of veterinary services, Uganda), director of veterinary services and animal husbandry, Uganda; L. U. Clarke (statistician, E. African Statistical Department), assistant director, E. African Statistical Department; H. J. Kitchener (game warden, Federation of Malaya), chief game warden, Federation of Malaya; R. G. H. Wilshaw (chief research officer, Agricultural Department, Federation of Malaya), chief registration officer, Federation of Malaya; H. Wright (drilling engineer, Geological Survey Department, Uganda), superintendent, rural water supplies, Geological Survey Department, Uganda; A. Gregor and D. A. Hutchings, veterinary officers, Northern Rhodesia; W. J. Herbert, veterinary officer, Nigeria; G. de G. Sieveking, curator, Department of Museums, Federation of Malaya; C. A. Smith, pasture research officer, Northern Rhodesia.

The European Cortina–Ulisse Prize, 1953

The European Cortina–Ulisse Prize of a million lire is awarded annually by the international journal *Ulisse* for a scientific publication. For 1953, the Prize is being given in co-operation with the Italian National Productivity Centre, and will be awarded for a work on economic and social science dealing specifically with productivity. Only books printed for the first time in Europe during the past five years will be considered. Three copies may be submitted by author or publisher, and must reach the Editor, *Rivista Ulisse* (Sezione Premio Europeo Cortina–Ulisse), 43 Corso d'Italia, Rome, by October 31.

"Library Co-operation in Great Britain"

Dr. H. T. Pledge, keeper of the Science Museum Library, writes: "Intending users of loan libraries may be misled by certain phrases on p. 1145 of *Nature* of June 27. It seems there to be implied that science loans are normally mediated by the National Central Library, so that a borrower's correct procedure is to apply to his local library. This, however, is only true of individual borrowers, for individuals cannot borrow direct from the Science Museum Library. Overwhelmingly the bulk of borrowing from this Library is corporate and is direct. The Regional–National Central Library system draws on a wider field, but, naturally, at the expense of promptitude. New research units should apply to the Science Museum Library direct, except for strictly medical literature, the best route for which is at present being re-examined".

Announcements

Dr. Julian Huxley has been awarded the Kalinga Prize for distinguished popular writing in science. The Prize of one thousand pounds sterling was established in 1951 as a gift to Unesco from Mr. B. Patnaik, Indian industrialist. The first award, in 1952, was made to Prof. Louis de Broglie, of Paris.

The following appointments have been made in the Queen's University of Belfast: Dr. W. M. Gibson (University of Bristol) and Dr. E. B. Armstrong (Armagh Observatory), to lectureships in physics; Mr. D. M. McDowell (consulting engineer), to a lectureship in civil engineering (hydraulics).

The George E. Davis Memorial Lecture of the Institution of Chemical Engineers will be given by Mr. Norman Swindin in the Reynolds Hall, College of Technology, Manchester, on October 10. Mr. Swindin is a former pupil of George E. Davis, a pioneer in chemical engineering and author of the two-volume "Handbook of Chemical Engineering", published in 1901.

The Société Française de Métallurgie will hold its autumn meeting in Paris during October 19–23. The Society would welcome the participation of British metallurgists, and those interested are invited to write to the Société Française de Métallurgie, 25 rue de Clichy, Paris 9^{e}.

ELECTRON OPTICS

SYMPOSIUM IN LONDON

A SYMPOSIUM on "Recent Research in Electron Optics", arranged by the Physical Society, was held during May 15–16 in South Kensington, London, in the Science Museum and in the Physics Department of the Imperial College of Science and Technology. About a hundred and fifty people attended. Of the twenty-two talks delivered, nine were concerned with pure electron optics, and the rest were devoted to a great variety of applications. Nuclear physicists learned about new developments in the design of accelerators and of β-ray spectrometers; electron physicists heard about measurements of quantum losses, scattering experiments, examination of luminescent semi-conductors and plasma oscillations in electron beams. Other talks were concerned with electron microscopy, X-ray production, and applications of electron optics in television and in valve design.

The meeting was opened with a short welcome of the visitors by Prof. R. Whiddington, the president of the Society, and by Dr. O. Klemperer, who had arranged the programme. The first four talks were on electron lenses. G. Liebmann[1] showed that very general practical formulæ can be given for presenting such properties as focal lengths, field distribution, errors, etc., of shielded lenses as functions of the magnetic gap-length, the diameter of the pole pieces and the excitation of the lens. Measured results deviate from these formulæ only when the saturation of the iron becomes substantial. Incipient saturation results in a loss of m.m.f., and at the pole-piece tips it has the effect of an apparent increase in lens dimensions. T. Mulvey[2] discussed the design of the magnetic circuit as the only efficient means of minimizing these saturation effects.

J. Ellis showed pictures and diagrams explaining the design of a large magnetic lens which is used in University College, London, for concentrating fast electrons or positrons from weak sources on to thin foils in order to study differences in scattering of these two kinds of elementary particles.

O. Klemperer[3] directed attention to the importance of line-focus lenses which project parallel rays into a focal line. The practical termination of 'two-dimensional' electrodes without introducing lens errors was mentioned as one of the practical problems. Results of measurements were given for the electrostatic plate lenses, box lenses and lipped lenses, and for the magnetic plate lenses, two-pole and four-pole lenses. Applications of line-focus lenses in a spectrometer, in an electron microscope and in a strong-focusing accelerator were shown in slides.

The following talks dealt with the corrections of aberrations. J. C. Burfoot[4] reported results of his theoretical studies on the possibilities of a correction of electrostatic lenses by abandoning rotational symmetry. He showed pictures of many queer equipotential surfaces which could produce foci without spherical aberration; none of these, however, could easily be applied to the design of practical lens electrodes. G. D. Archard discussed various possibilities of deviations from circular symmetry, leading to astigmatic foci. He demonstrated by means of a large plaster model the classifications of elliptical distortions and of corrugations of the end faces of electrodes or of pole pieces, and he explained the different kinds of magnetic and electrostatic 'stigmator' devices which have been used successfully in electron microscopy for the correction of this asymmetry error. J. E. C. Jennings remarked that every solenoid, even under conditions of best possible circular symmetry, would produce (probably due to the helical nature of the coil) an astigmatic focus. On the other hand, line-focus lenses can easily be obtained by winding the solenoid on to an asymmetric former—for example, of rectangular cross-section.

B. J. Mayo was concerned with the image curvature of electrostatic immersion lenses. Though, theoretically, a completely flat image field cannot be obtained with such lenses, some progress with the reduction of the curvature has been achieved by using first an accelerating lens for converging the pencils towards the axis and then a decelerating lens for focusing the pencils on to the image surface.

In the next section, devoted to the electron gun, M. E. Haine[5] reported his experiments with P. A. Einstein on a three-electrode, high-voltage emission system with a hairpin cathode. Maximum intensities of 10^4 amp./m.^{2} per unit solid angle have been obtained under optimum operating conditions for beams of a Gaussian angular current distribution. For high-beam currents at reduced bias, hollow beams were observed, the formation of which was derived from a marginal emission of electrons with outward radial velocity components running into a strongly converging field deflecting them across the axis. L. Jacob[6] spoke about the emission characteristics of low-energy guns with oxide cathodes. Maxima and minima in the angular distribution of beam current density were thought to be caused by plasma oscillations.

The following two talks dealt with the focusing in accelerators. F. K. Goward gave some information about the strong-focusing synchrotron project. The scheme is essentially based on an alternation of magnetic guide fields of very large positive and negative field index (n) in successive sectors of the orbit. However, the very high n-values and a correspondingly very large orbital radius, as visualized by Livingstone, the originator of the scheme, cannot be realized in practical machines owing to correspondingly minute tolerances for machining and alignment of the pole-pieces[7]; the projected machine has to be built on a more modest scale than was hoped for originally. J. S. Bell[8] discussed the application of the strong-focusing principle to the design of a linear proton accelerator, and recommended the use of electrostatic four-pole lenses which can be operated at relatively modest voltages.

In the following section on electron optics in television tubes and valves, L. S. Allard discussed the requirements for, and the limitations of, electrostatic and magnetic deflectors, especially in connexion with problems introduced by wide-angle scanning. He demonstrated a cathode-ray tube containing a fluorescent screen arranged tangentially to the deflected beam so that the defocusing effects introduced by the deflector could be seen at large deflexion angles. B. Meltzer spoke about certain time-lag phenomena which are most troublesome in the pick-up of rapidly changing scenes by television cameras. These are due to the fact that a mosaic element on the signal plate is not discharged at once after cessation of the illumination, but only after several consecutive scans. The signal lag is found to be the shorter the larger the scanning current that can be concentrated upon the element; hence the limits to the reduction of the lag are set by electron optical conditions. The quality of the focus is known to deteriorate with increasing temperature of the electron beam. Apparently, owing to space-charge interaction, the beam temperature has been found to be much higher and to increase much more rapidly than the temperature of the cathode. C. S. Bull reviewed some applications of electron optics to valves: for example, the focusing by valve grids and the effects of an alignment of these grids. He also discussed the design of thermionic multiplier valves and of counting tubes[9], and he reported some recent attempts to increase the slope in deflexion valves with the help of space charge[10].

In the next section, G. W. Jull described his experiments with a velocity spectrograph with helical axis originally designed by D. Gabor, in which focusing deflexion is effected between cylindrical condenser plates; a change of 1 volt can still be detected at an electron energy of 1 keV. The use of this spectrometer was illustrated by experimental curves showing the small quantum losses which are known to occur at the transmission of electrons through thin foils. R. E. Siday discussed the accuracy of his absolute method for measuring β-ray energies[11], a method which depends on recording the angular rotation of a line image by a solenoidal field of exactly known magnetic potential difference. J. E. C. Jennings[12] gave a short survey of his theoretical and experimental investigations on the deflexion focusing errors of circular magnetic prisms.

Then followed two talks on fine electron foci. V. E. Cosslett[13] discussed the ultimate limits of obtainable current density ($> 10^7$ amp./cm.^{2}) when these foci are scaled down to smallest diameters (< 1 micron) by the best available lenses at the greatest possible emission density from a hairpin cathode. These minute foci were shown to be very useful for producing sharp and intense shadow images in the electron point-projector or in the X-ray shadow microscope. W. Ehrenberg explained the use of these fine-electron probes for the investigation of semi-conductors. He showed photographs taken through a microscope from which the depth of penetration of the electrons into a fluorescent transparent solid could be gauged.

J. W. Menter[14] reviewed recent progress of the direct electron optical method for examination of solid surfaces. An electron beam of 50–100 keV. reflected at an angle of a few degrees from a specimen passes through the objective and projector lens of a highly magnifying electron microscope. Maximum intensity of reflexion occurs apparently at the glancing angle. The reflected beam consists of inelastically scattered electrons which have suffered losses of the order of 100 eV. Slides of excellent microscope photographs were shown in which the resolution in some cases reached about 100 A.

G. Liebmann showed slides and explained the design of the large resistor-network analogue which he has built up in the laboratories of Associated Electrical Industries at Aldermaston. This network is being used now to a great extent for solving electron optical problems—for example, for the determination of field distributions in electrostatic and magnetic lenses, especially when these are loaded by space charge.

Finally, P. A. Sturrock, speaking on some prevalent misconceptions in electron optics, directed attention to the confusion which surrounds some formulæ for focal length of electrostatic lenses. He also discussed the necessity for a clear distinction between dispersion and chromatic aberration of systems with curvilinear axis such as the semi-circular deflexion spectrometer.

Many of the items in this meeting were already known to the experts in the particular subject. However, the contents of the talks were always concerned with very recent developments—often still of controversial nature. For this reason the discussion was vivid throughout, and it was not difficult to establish contact between workers in widely diverging fields who were all joined by a common interest in electron optics.

THE SCIENTIST'S RESPONSIBILITIES*

By Dr. R. L. M. SYNGE, F.R.S.

It is fashionable among critics and broadcasters nowadays to speak patronizingly and almost contemptuously of the great rationalists of the nineteenth century—one thinks first of T. H. Huxley—who believed that the advance of our understanding of Nature opened to mankind a great prospect of material and ethical improvement. It is maintained that this was a delusion, and more compromising views about the nature and function of science are aired. The critics have not noticed that the intellectual giants, who were at work during the nineteenth century in the most advanced country in the world, have only in recent years achieved world-wide recognition. They believed that human troubles were to be overcome by human ingenuity rather than endured while blaming or accepting the 'will of God'. Just because here in Britain we have not achieved progress commensurate with what these prophets expected, we fail to see what a revolution there has been in the attitude of the millions of the depressed peoples of the world, and that it is to a great extent their unwillingness to go on accepting fatalistically their various troubles that has had effects on our own economic position and self-assurance. The change in the terms of our trade, consequent on a greater inclination by other nations to industrialize themselves and to eat more of the food they produce themselves, is for us the long-term background of the past fifty years; against this background we have two ruinous wars, the slump of the 1930's and the war preparations and threat of war of the present years.

---

* Substance of an address given at the National Conference of "Science for Peace" in London on March 14.

The marvellous developments of science and technology during this same fifty years have not brought to us the benefits people were justified in expecting; benefits there have been, all the same, and it is typical of our nature to under-estimate them. But the main applications of the advances in pure science have been towards the technology of war, and this has been the most striking in the most recent years. Before the Second World War the application of science suffered from neglect; during and since the War, the official attitude changed—governments had at last learnt something of the power of applied science, and now to a great extent they are directing it towards objects that at best are unproductive and wasteful and at worst could bring about destruction on an unprecedented scale. On the surface at least, cynicism about the role of science has some justification.

The scientists themselves must bear some of the blame for the prevalent attitude. The detailed solving of *any* scientific problem is an absorbing pursuit, and it is very easy to bury oneself in the minutiæ of scientific research and not see the wood for the trees. It is widely maintained that "the scientist establishes facts: other sections of society make what use of them they will, and that use is to a great extent unpredictable". I think this is a serious under-estimate of the scientist's vocation. Admittedly he works within the framework of objectively ascertained facts, and admittedly there is a big element of unpredictability in the implications of any new discovery. But Nature is so complicated and manifold that those aspects or facts that a generation's work can hope to reveal are only a minute proportion of what is waiting there for future generations. Some of the spectacular advances of recent years have induced a sort of intellectual arrogance among scientists, an over-estimation of the extent of our understanding of Nature which leads them to under-estimate the enormous choice of pathways of experimentation and observation which lies open to us. This leads to a very routine approach to experimentation, and one which is much subject to crazes. Some fields of study are worked to exhaustion and others are neglected. The desire of those who finance research for immediate practical results is only partly to blame for this. Scientists must come to feel much more responsibility for *what* facts are ascertained, that is, for the direction taken by the progress of science. I will return later to some consequences of this for British science in particular.

The other stock answer of the scientist wishing to evade responsibility is "As a scientist . . . I have no more right than any other citizen to a special say in how public affairs are run". This often means "I am willing to be as dumb as other citizens while public affairs are mismanaged, even when it concerns matters of which I have special knowledge". Actually, of course, very serious pressures exist which prevent public comment by many of those best able to judge (for example, Civil servants) when affairs are being grossly mismanaged. One wonders how many appropriations of public funds comparable to the groundnut scheme are kept dark as a result of the Official Secrets Act or of the fear of loss of employment. I am far from claiming as desirable the substitution of politicians by scientists; but I do think scientists should be far more vocal than they are about matters of public interest where they have special knowledge. These are many and important. In work of this kind the different organizations of scientists can do great things, and this includes Science for Peace. I would like to congratulate the Committee on what it has done so far in getting important information and issues publicly dealt with.

The main problem which now faces us is the threat of war and the use in war of weapons having a new order of destructiveness. The problems raised by these new possibilities of waging war have been discussed at length by all manner of people. The bulletin of Science for Peace[1] has contained recently quite a lot of discussion of the "justification" for the use of one kind of weapon or another and of the ethics of scientists working on the elaboration of such weapons. My own view is that this sort of argument is rather sterile and not particularly helpful in the present situation. I maintain that many of the weapons the use of which is contemplated would have effects that are entirely unpredictable, and that whoever might be concerned with using them would be faced with charges not only of inhumanity but also of jeopardizing the future of the human race for generations to come. The greatest danger seems to come from radioactive substances and from ionizing radiations. But I do feel that the most important activity for us here and now is to work to put a stop to existing wars and to prevent future wars by agreement between the nations. That is why I support the British Peace Committee and, through it, the work of the world peace movement. The Press of Great Britain indulges in abuse of this movement, but is particularly careful not to mention its programme. This is the minimal programme I have just mentioned, and, being minimal, it obtains maximal support among all the nations of the world. It aims at the negotiation of a pact between the nations which will effectively prevent the use of war for the settlement of questions at issue. The very destructiveness and inefficiency of war for settling questions at dispute is more than ever manifest to the peoples of the world, and they are increasingly impatient with the present poker game of war preparation which is an oppressive burden to most people and likewise settles nothing. A genuine settlement could lead to satisfactorily controlled disarmament all round and to an effective control and accounting of radioactive materials. I cannot feel that after such a settlement the risk from biological warfare, the materials of which are admittedly difficult to control, would be a very great one. Such an international settlement is particularly important for Britain; in view of our high population density and our dependence on foreign trade we would be far more than averagely vulnerable in the event of full-scale war. Quite apart from its crippling effect on our economy, the contribution of successive British governments to the poker game by going in for constructing atom bombs is pathetic from this point of view.

Of course, I know that the preparation of expensive armaments is advantageous to various individuals, and also that should it cease the economy of the United States would be faced with serious problems of readjustment. But this is not sufficient to justify what is a serious economic burden carrying with it a still more serious threat for nearly every nation in the world.

This seems to me to be the immediate objective to work for; since if it can be attained the other secondary troubles which affect the scientist will in large measure fall away. These troubles, refusals of passports and visas, secrecy of scientific work, lack of freedom to publish (with its bad consequences for the individual trying to change his job), are things that really hurt scientists. We have a big job to do upholding the decencies of our profession and trying in all ways open to us to maintain the international unity of science against those influences that are trying to stifle it. But I think it is an illusion to suppose that ours is more than a delaying action; a delaying action which only makes sense on the supposition of an end by international agreement to the war preparations.

My own view about improving international relations and opening the way towards such an agreement is that the best hope lies in recognizing how firmly nationalist feeling is entrenched in the world to-day. My travels have extended only from the Alps to the Arctic Ocean and from Poland to Ireland, but even within that narrow compass there is plenty of nationalism, and it does not seem to be associated with any particular system of government or religion. To advocate a balanced national economy and truly reciprocal trading relations with other nations is not an inspiring doctrine compared with ambitious schemes for world or continental federation, international plans for reconstruction, and so forth. But I cannot help feeling that it is the path for true internationalism at the present time, and that these more grandiose proposals are very often suspect as projects for veiled interference by foreigners in a nation's own affairs. In particular, I think it is highly indiscreet for citizens of Britain to preach to other nations, particularly Asiatic nations, the neo-Malthusianism that has recently become so fashionable. Two members of the Committee of Science for Peace, F. le Gros Clark and N. W. Pirie, have done an excellent job in bringing together a number of gifted authorities on food[2] to show that these are problems for the coming two generations. It is for us to ensure their survival in an undamaged world. With them, we can all express our gratitude to Lord Boyd Orr for his evangelism for food and his respect for humanity all over the world.

While working towards really effective international agreement, we could well take steps to put our own national affairs in order. It has not been convincingly shown that even under existing conditions a smaller military expenditure could not be used to ensure more effectively our national security. At the same time, tensions due to the presence of our forces in the territory of other nations could be relaxed. We could also assert our sovereignty in our external trade, make suitable long-term trade agreements and keep them scrupulously. Such measures would permit at least the beginning of a departure from being chronically on the brink of bankruptcy, as well as contributing substantially to a diminution of international tension. We could then set about some of the jobs that are crying out to be done. Foremost of these is to stop cutting the education of our children. Of all the various forms of pound-foolishness in which we are involved at the moment this seems to me the one that will have the worst results in the long run. But we could also make a start on the long overdue improvements in most of our industrial capital equipment, and particularly in our use of fuel. Agriculture could also absorb a lot of capital with advantage. Once a government could show that it had some faith in the future, stemmed the inflation and produced a standard of living that rose rather than fell, plenty of people would be ready to put savings into productive projects of this kind. So far as scientists are concerned we have at this moment, with our tradition of all-sided fundamental science, a magnificent basis for developing those newer branches of technology that will be needed. New branches of pure science will also need cultivation. We have rather a good reserve of trained people who could do with wider scope for their abilities. We might even have a few over for helping other nations should they ask for such help.

Very few of the matters I have been discussing concern scientists alone. But progress on all of them would be more rapid if scientists were more upstanding and vocal about them; if, in fact, they took a more serious view of their responsibilities.

RESEARCH DEVELOPMENT IN THE MACHINE-TOOL INDUSTRY OF THE U.S.S.R.

In an editorial in the Russian machine and tool journal, *Stanki i Instr.* (24 (1), 1; 1953), which is the official organ of the U.S.S.R. Ministry of Machine Construction, a directive is quoted of the nineteenth Session of the All Union Party on the progress of the current five-year plan (1951–55) as follows: "[Among our immediate objectives are] to improve the work of the scientific research institutes and the scientific labours of the highest scholastic establishments; make fuller use of the powers of science to solve fundamental questions in development of the national economy; make more generally available the most advanced engineering practice; and ensure wider practical use of scientific discoveries; moreover, to assist in every way the teaching profession to work out their theoretical problems in all branches of knowledge, and to strengthen the union of science with industry".

In the report on the work of the Central Committee of the Communist Party of the Soviet Union (VKP), Mr. Malenkov is quoted as emphasizing that, in the struggle for further technical progress, science must play a much greater part. Only thus will the Soviet people more fully discover and better utilize the great wealth and powerful forces of Nature. Much success has been already achieved in recent years of the greatest importance in the Soviet economy. At the same time, he revealed also certain defects and weaknesses. Incidentally, it may be observed that, at the eighteenth Session of the Party, Malenkov had a great deal to say by way of censure for slackness and bad management in certain branches of industry (quoted in a recent issue of the journal of the glass and ceramic industry, *Steklo i Keramika*).

The editorial proceeds to exemplify this closer union of research and industry by a brief review of the work of the various institutes associated with the Ministry of Machine Construction. Among these are: the Experimental Scientific Research Institute for Metal-cutting Machines (ENIMS), the Scientific

Research Institute for Tools (VNII), and the Scientific Research Institute for Abrasives and Grinding (VNIIASH). The relevant branches of manufacture receive regularly from these and other establishments information and examples of products and processes whereby labour efficiency can be raised, metal-working and the like improved, etc. Special attention is given to mechanization and automatization of methods. In addition to the three technical institutes mentioned, there is also a fourth which appears to fulfil the functions of a standardizing office, this being the Bureau of Interchangeability (BV). A great part of the work of all is concerned with components for electric motors and for the automobile and tractor industries, with formulating the best types of mass-production lines and working cycles, and in developing new machines and methods generally.

More specifically, the Abrasives and Grinding Institute has established the conditions for producing abrasive particles of given qualities and characteristics whereby grinding and polishing can be much more accurately controlled than was hitherto possible. Further details of its work were given in a report on the Russian abrasives industry (*Stanki i Instr.*, 23 (12), 6; December 1952). Reference is made to a large number of different types of new machines, tools and instruments, supplied to various factories in 1951 and 1952, including some woodworking and foundry equipment by the respective institutes for these two branches of industry. Details with drawings of some of these were published in *Stanki i Instr.* during 1952.

Yet it is complained that the introduction of new methods and improved equipment proceeds much too slowly, at all events in some of the engineering works, and there is considerable room for speeding-up and more efficient management in this direction. The same criticism has been noted in other industries—for example, in some of the glass and ceramic factories—according to the official journal for these. As has been stated above, it was voiced by Malenkov at the eighteenth Session of the Party in 1951. For example, some of the comparatively new designs from the metal-cutting machines institute, evolved five or six years ago, for high-efficiency worm-gear modular milling machines, permitting rates of feed two or three times greater than hitherto, have only very tardily been adopted ("become familiar") in general practice. More particularly in the machine construction works, the results of research, including new and improved types of high-efficiency gear-cutting machines, undertaken by the tool research institute and the Novo-Kramatorsk heavy machine-tool factory of the Ministry, have been practically ignored.

The improved ceramic-tipped or -faced cutting-tools designed by the abrasives institute, more especially those with thermo-corundum tips, should be much more widely adopted. These tools can replace those of high-speed steel and hard metals very often to great advantage both in high finish and semi-finish work, and thus ensure considerable economy in tungsten, titanium, cobalt and other materials in short supply. The real fault sometimes may lie with the institute concerned and its associate works, for, although it appears a little ambiguous, the statement is made to the effect that the abrasives institute, for example, together with the principal abrasive factory (Glavabraziva), produce totally inadequate supplies of high-speed grinding wheels (this, of course, may be partly due to lack of demand), and the metal-cutting machines institute is also charged with slackness in production.

It is suggested that, for speeding-up the more general adoption of better methods and equipment, the institutes concerned must maintain closer liaison with the factories, from the very beginning of their research along any particular line. This should be to the mutual advantage of both sides. More especially the workers themselves in the factories should be interested in, and attracted to, new developments. (Incidentally, it may be mentioned that one means of doing this in the machine-tool industry, to which reference is made from time to time in the technical press, is the organization of prize competitions for improved machine designs, although these may be limited mainly to the higher ranks of foremen, managers and draughtsmen.)

The scientific research establishments are directed to make wider use of possibilities suggested to them in the instructions and directives issued by the Ministry of Machine Construction. These directives apply also to the factories, and charge them with definite responsibilities in regard to the introduction of results obtained in the research institutes. It is a binding obligation on every worker, both in the institutes and in the factories, to make the fullest use of such results, described as the most powerful aid towards further engineering progress.

TRANSFERASE ACTIVITY OF HYDROLYTIC ENZYMES

By Dr. R. K. MORTON

School of Biochemistry, University of Cambridge*

In recent years there have been a number of experimental demonstrations that certain preparations of hydrolytic enzymes may catalyse the formation of new compounds by transfer of a group from a 'donor' compound to a suitable 'acceptor'. While this 'transferase' activity was found to be associated with certain preparations of β-glycosidases[1], proteinases[2], and acid[3,4] and alkaline[5] phosphatases, the relationship between the enzymes catalysing hydrolysis and transfer was by no means clear. The exchange reaction has been ascribed to the combined action of two enzymes[1], to specific transferring enzymes[4] and to the hydrolases themselves[2,3,5]. A detailed study of the action of highly purified alkaline phosphatase has therefore been carried out in this laboratory. The results, which are summarized in this article, indicate the probable mechanism of the exchange reactions. They have been briefly reported elsewhere[6].

Transfer Reactions catalysed by Alkaline Phosphatase

The alkaline phosphatases of both cow's milk and calf intestinal mucosa were purified to obtain essentially electrophoretically homogeneous proteins, using procedures already briefly described in *Nature*[7]. Synthetic creatine phosphate, glucose, magnesium acetate, and veronal buffer were incubated with the purified enzyme at pH 9·6 and at 37° C. for 2–5 min.

---

* Present address: Department of Biochemistry, University of Melbourne.

Inorganic phosphate and creatine liberated were determined colorimetrically[8,9] and hexose phosphates were estimated enzymically[10]. The products were creatine, inorganic phosphate and glucose-6-phosphate only. Under the reaction conditions used, which were designed to measure true initial velocities, there was no detectable hydrolysis of the ester phosphate formed by transfer.

The initial experiments clearly established that both milk and intestinal phosphatases catalysed two reactions simultaneously :

creatine phosphate + water →
inorganic phosphate + creatine (*A*)

creatine phosphate + glucose →
glucose-6-phosphate + creatine (*B*)

When creatine phosphate was replaced by inorganic phosphate at the same (or at lower) concentrations, but with other conditions unchanged, there was no synthesis of glucose phosphate. Moreover, the addition of inorganic phosphate to the reaction mixture containing creatine phosphate appreciably inhibited both the hydrolytic and the transferase activities. Under the conditions employed, therefore, all new ester (equation *B*) was formed by direct transfer of the phosphate group.

In contrast with other investigations[3,4,11], the procedures employed in this study permitted measurement of the true initial rates of both the hydrolytic and transferase reactions. The initial velocities were determined using various donors (containing both high- and low-energy phosphate bonds), such as creatine, phenyl and glycerył phosphates, and a number of different acceptors, such as glucose, fructose and glycerol. The results of these kinetic studies, which are summarized below, show the influence of a number of important factors on the transferase reaction.

Acceptor concentration. The data obtained using glucose as acceptor, and with creatine phosphate as donor, are typical and are illustrated in the accompanying graph. It is seen that, up to 2 *M* glucose, the initial rate of hydrolysis, that is, the liberation of inorganic phosphate, declines with increasing concentration of glucose, while simultaneously the initial rate of transfer, namely, glucose phosphate formed, increases. Hence there is little change in the rate of creatine liberation. Between 2 and 4 *M* glucose both the rates of hydrolysis and of transfer decline, apparently through non-specific effects of the high glucose concentration. However, the percentage transfer, that is, the ratio (μmoles glucose phosphate formed × 100)/μmoles creatine liberated (compare ref. 3), increases with increasing glucose concentration to a maximum value at about 2 *M* glucose and is unchanged by further increase of glucose concentration.

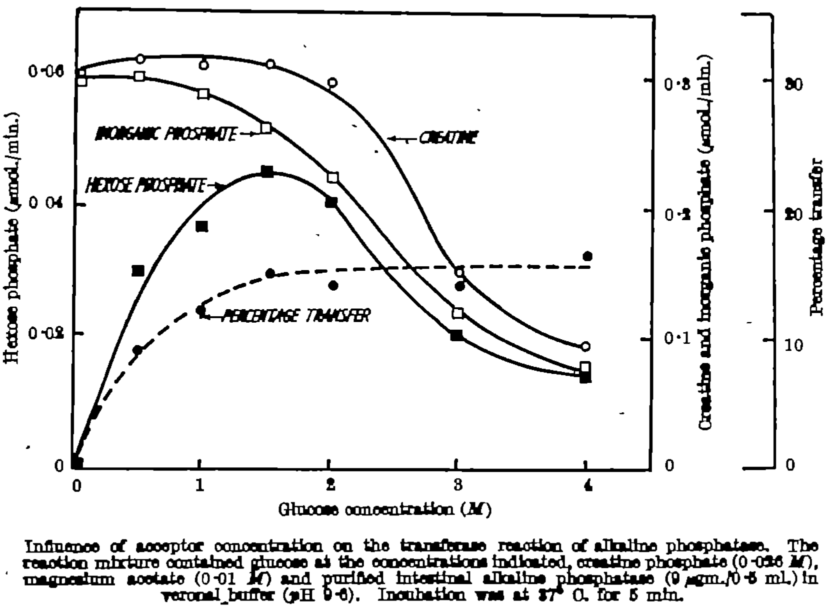
Essentially similar results were obtained with both fructose and glycerol, although the maximum percentage transfer differed from that obtained with glucose. However, no phosphorylation could be demonstrated when sucrose was used as an acceptor. Although sucrose was not phosphorylated, there was a continual decline in the rate of hydrolysis with increasing sucrose concentration, as noted with glucose.

Donor concentration. Both the initial rates of hydrolysis and of transfer were similarly influenced by changes in the donor concentration, and thus the percentage transfer remained independent. Similar findings have been reported for acid phosphatase[3]. The contrary findings by other workers[11] were no doubt due to the fact that true initial reaction-rates were not measured.

Hydrogen-ion concentration. Over the range *p*H 8·0 to 10·2 the percentage transfer was found to be independent of *p*H. The dependence of percentage transfer on *p*H found for plant acid phosphatases[3] was later attributed to the influence of *p*H on the bond energy of the donor[12]. However, as shown below, the donor bond energy does not determine the percentage transfer.

Nature of the donor. It has been claimed that the bond energy of the donor determines both the rate and efficiency of the transferase reaction catalysed by alkaline phosphatase[4], although the importance of the enzyme specificity in relation to the rate of reaction has been recognized[13]. However, the results given in the accompanying table show that the percentage transfer obtained with alkaline phosphatase is independent of the donor bond-energy. Thus, provided that true initial rates are measured, not only does β-glycerol phosphate give the same percentage transfer to glucose as does creatine phosphate but, indeed, the rate of the reaction with glycerol phosphate is very much greater than with creatine phosphate. The latter is a relatively poor substrate for alkaline phosphatase. It should be noted that the transfer from β-glycerol phosphate to glucose forms an ester of higher bond-energy than the donor.

Only those substrates which are hydrolysed by the enzyme, namely, true orthophosphomonoesters, phosphoamides, and related compounds such as



Influence of acceptor concentration on the transferase reaction of alkaline phosphatase. The reaction mixture contained glucose at the concentrations indicated, creatine phosphate (0·036 *M*), magnesium acetate (0·01 *M*) and purified intestinal alkaline phosphatase (9 μgm./0·5 ml.) in veronal buffer (*p*H 9·6). Incubation was at 37° C. for 5 min.

RELATIONSHIP BETWEEN PHOSPHATE BOND ENERGY OF THE DONOR AND THE PERCENTAGE TRANSFER WITH ALKALINE PHOSPHATASE

Donor phosphate	Apparent $-\Delta F^{*}$ at pH 9·0 (calories)	Per cent transfer, estimated from initial velocity of reaction using 2 *M* glucose as acceptor
Creatine phosphate	14,000	14
Phenolphthalein phosphate	?	14
Phenyl phosphate	4,200†	18
Glucose-6-phosphate	3,000	—
β-Glycerol phosphate	2,200	16

* See refs. 18 and 24.
† Value estimated from published data for *p*-nitrophenyl phosphate[11].

phospho-enolpyruvate, act as donors for the transferase reaction. Since pyrophosphates are not attacked by the purified enzyme, neither hydrolysis nor transfer occurs when either adenosine tri- or di-phosphates are used as donors. However, adenosine-5-phosphate is a suitable donor, and shows similar percentage transfers to those found with other ortho-monophosphates.

There is evidence that the product of the transferase reaction with β-glycerol phosphate as donor and glycerol as acceptor is α-glycerol phosphate. Thus alkaline phosphatase catalyses a 'phosphomutase' reaction.

Results with other Phosphatases

At pH 5·5 partially purified acid phosphatase from human prostate gland gave essentially similar results to those obtained with alkaline phosphatase at pH 9·6. Using the acid phosphatase, β-glycerol phosphate gave the same percentage transfer to glucose as did creatine phosphate, and the product in each case was glucose-6-phosphate (compare ref. 3).

No transferase reaction could be detected when the phosphatases of narrow substrate-specificity, namely, kidney hexose diphosphatase, 5-nucleotidase from bull testes, and muscle myosin – adenosine triphosphatase were used with their appropriate substrates and either glucose or glycerol as acceptors. Other workers[13] have reported that they were unable to demonstrate any transferase activity associated with the substrate-specific inorganic pyrophosphatase of yeast.

There was little or no decline in the rate of hydrolysis by such substrate-specific enzymes in the presence of quite high concentrations of potential phosphate-acceptors, such as glucose, glycerol and sucrose. In this respect these enzymes differed markedly from the enzymes of wide substrate-specificity (acid and alkaline phosphatases).

Mechanism of the Transferase Reaction

The above results show that certain compounds containing hydroxyl groups can successfully compete with water for a site at the enzyme surfaces of the alkaline and acid phosphatases, but not at those of the substrate-specific phosphatases. The group-specific acid and alkaline phosphatases clearly have a measurable affinity for acceptors, such as glucose and glycerol, as well as water, and it is suggested that the enzymes which show strict specificity toward the donor also show strict specificity toward water as the phosphate acceptor.

Kinetic studies suggest that the reactions of the acid and alkaline phosphatases may be described by the following equations:

$$E + RP \rightleftharpoons E.RP \qquad (1)$$

$$E.RP \rightleftharpoons EP\ (+\ RO.H) \qquad (2)$$

$$EP + \mathrm{H.OH} \rightleftharpoons EP.W \qquad (3)$$

$$EP.W \rightarrow E + \mathrm{H}P \qquad (4)$$

$$EP + R'.\mathrm{OH} \rightleftharpoons EP.A \qquad (5)$$

$$EP.A \rightarrow E + R'P \qquad (6)$$

where E is enzyme; RP is substrate (phosphate donor); $E.RP$ is enzyme-substrate complex; EP is phosphorylated enzyme; $RO.H$ is liberated alcohol; H.OH is water; $EP.W$ is phosphorylated enzyme–water complex; HP is inorganic phosphate; R'.OH is acceptor; $EP.A$ is phosphorylated enzyme-acceptor complex; $R'P$ is acceptor phosphate (newly-formed ester).

The first reaction is probably the formation of an enzyme-substrate complex $E.RP$ (equation 1), which gives rise to a further complex EP (equation 2). Since acid and alkaline phosphatases catalyse syntheses from inorganic phosphate, the latter must be regarded as a substrate of the enzyme, and H may be substituted for R in equations 1 and 2 above. The same complex, EP, is probably formed in both cases.

Some consideration has been given to the nature of the complex EP. Data obtained during these studies suggest that the enzyme may be phosphorylated following combination with the substrate. The complex EP therefore may represent the 'active enzyme' which contains a reactive phosphate group (possibly formed by phosphorylation of the phenolic hydroxyl of a tyrosine residue). This would be consistent with the important findings of other workers[14,15] that acid and alkaline phosphatases cause cleavage of the —O—P— bond of the substrate.

It is suggested that when acceptors, such as water or glucose, are activated at the enzyme surface by forming the complexes shown in equations 3 and 5, the reactive phosphate group passes to the acceptor, thus forming either inorganic phosphate or a new ester (equations 4 and 6).

Catalysis by the substrate-specific phosphatases may be described by equations 1, 2, 3 and 4. Since these enzymes have a relatively poor affinity for acceptors other than water, the addition of compounds such as glucose or glycerol, even in very high concentration, has little effect on the rate of hydrolysis. In the case of hexose diphosphatase, the combination between the enzyme and substrate probably involves an —SH group[16], and EP may well represent the 'active enzyme' which contains the thioester group $-\mathrm{S}-\mathrm{PO_3H_2}$. It has been shown that —SH groups are not involved in the combination of alkaline phosphatase with its substrates[17]. The need for the formation of a thioester bond, rather than a phenolic phosphate, is probably related to the differences in substrate specificity shown by hexose diphosphatase and alkaline phosphatase. In this connexion, it is noteworthy that the phosphokinases, which are all highly specific toward both donor and acceptor, appear to require integrity of —SH groups for combination between the enzyme and substrate[17,18].

A number of transfer reactions have been reported to be catalysed by various hydrolytic enzymes other than phosphatases. It seems likely that essentially similar mechanisms to those described above may be involved in the transfer reactions reported for enzymes such as β-glycosidases[1], fructo- and gluco-invertases[19,20], some proteinases[2,21,22] and certain peptidases[23]. All the hydrolytic enzymes for which transferase activity has been described exhibit a rather wide specificity toward substrates. It seems very likely that, in general, the hydrolases of very narrow substrate specificity will be found to be devoid of associated transferase activity. In view of the evidence obtained with purified alkaline phosphatase, there seems no good reason for attributing any longer the transferase activity to enzymes associated with, but distinct from, the hydrolases.

This work was commenced while holding a travelling scholarship awarded by the Gowrie Scholarship Trust of Australia. It was completed while receiving a grant from the Agricultural Research Council of Great Britain. The assistance of both these organizations is gratefully acknowledged. I also wish to thank Dr. M. Dixon for his encouraging interest and advice throughout this work, and Dr. E. C. Slater for valuable advice on enzymic methods for the estimation of hexose phosphate. [Jan. 13.

BASIC MAGMA CHILLED AGAINST ACID MAGMA

WE, Wager in St. Kilda and a little later Bailey at Slieve Gullion, have recently been led, quite independently, to a novel conclusion concerning local inter-relations of certain basic and acid igneous rocks belonging to the British Tertiary province. Evidence from opposite ends of the province, 250 miles apart, forced us to postulate chilling and crystallization of basic magma against acid magma. We were at first reluctant to do this, but on second thoughts both of us, again independently, realized that since the temperature-range of crystallization for basic magma is a hundred or so degrees higher than that for acid magma, it is not unreasonable to postulate chilling of basic magma against cooler, but still liquid, acid magma.

The St. Kilda evidence comes from the complicated belt of rocks mapped by Cockburn[1] which lies between the earlier eucrite and the later Conachair granophyre. The chief rock in this zone is a fine-grained gabbro or dolerite, which has been extensively injected by microgranite, often with much interaction between the two (ref. 1, pp. 516–20, 530–33, 538–39). In addition, Cockburn has distinguished a fine-grained olivine–basalt intimately associated with the microgranite; it is the special relationships of the latter which in St. Kilda led to the new concept.

In the field, acid material often veins the basalt, showing that the acid magma was mobile after the basalt had solidified, but occasional critical pieces of field evidence indicate additional complications. Thus along the western shores of Village Bay and in the Dun Passage, the olivine–basalt material often occurs in the microgranite as series of alined blocks, among which individual blocks are either rounded or have one side cuspate to fit the rounded form of a neighbour. Some of the rows of blocks are believed to have resulted from basic magma injected into the acid magma, like pillow lava into water, but this arrangement apparently grades into others which are interpreted as the result of the pulling apart of the partly solidified basic magma during flow of the enclosing more acid material. The tearing apart sometimes occurred when the basic material was still essentially fluid, giving a string of blocks, more or less rounded; at other times it affected material that was essentially solid, when more angular blocks have resulted.

Textural relations vary correspondingly. In some cases the selvedge of the basic rock becomes increasingly fine-grained towards the margin for half a centimetre or so, as is clearly apparent both in the field and under the microscope (Fig. 1). The selvedge then reproduces the familiar effects of chilling of basic magma as seen elsewhere in small dykes and sills intruded into normal country rock. It is therefore in the present instance attributed to chilling of the basaltic magma against the adjacent acid. Where, however, the basic magma had solidified and then been fractured and penetrated by the still liquid acid magma, it does not show a fine-grained selvedge. Moreover, the acid material, often heterogeneous due to contamination with the earlier dolerite, does not in any circumstances show signs of chilling at its

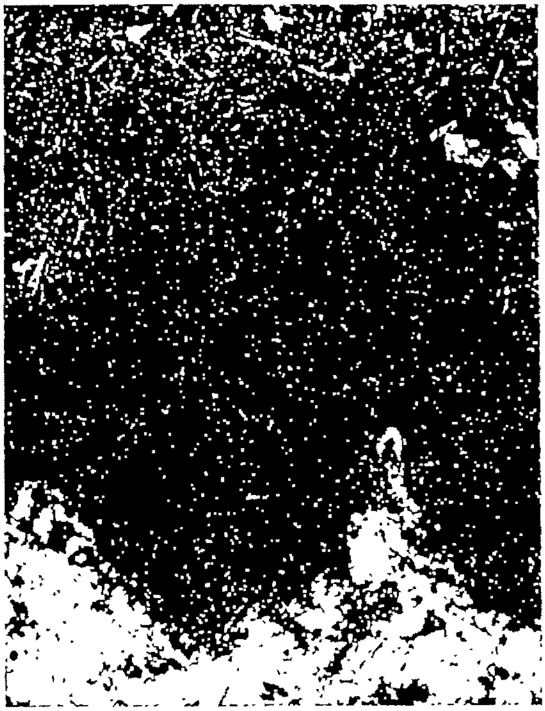

Fig. 1. Chilled contact of basalt against microgranite, 50 yards south of point where rocks first appear in position, south side of Village Bay, St. Kilda (× 7)

contact with the basalt; and its additional contamination in this position is only on a microscopic scale. The interest of these various phenomena was fully realized in the field, so that contacts were repeatedly examined. Eventually two cases of dyke-like masses of basic magma were found cutting acid rock and hybrid. There was definite chilling of the margin of the basic dyke, and yet acid magma was afterwards injected along occasional tears in it. Instances of this sort are likely to be rare, because there was much movement capable of tearing the basalt injections into detached blocks.

The chilled appearance of the contacts here described might be thought of as perhaps originating through metamorphism or metasomatism; also other explanations might be offered for the strings of rounded or cuspate inclusions of the basaltic rock in the acid. Several tentative hypotheses were tried in the field, but the one accounting most satisfactorily for the diverse and complex contacts between the basaltic rock and the microgranite starts with injection of basic magma into still hot and mobile acid material, with some rapid crystallization of basalt at the contact due to a certain degree of chilling. Subsequent movement has often involved the tearing apart of the basalt at different stages in its solidification, and this has given another type of basalt–granite contact without evidence of chilling.

At Slieve Gullion the idea of basic magma chilling against acid arose out of consideration of certain relationships recently described by Doris Reynolds[2]. She has in places identified what she takes to be chilled pillowy surfaces of basic lava, which latter, she thinks, has been metamorphosed, a few inches away, into hypersthene–dolerite. Against the chilled surfaces she found that granophyre has not infrequently crystallized; and within the chilled zones she recognized indications of contact-alteration, including micro-granulitization of augite rods (ref. 2, pp. 91, 96–98, 119, 133, 140). A visit to three cited localities showed that appearances do not correspond closely with those presented by pillow lavas in other parts of the world. The differences are, in fact, so great as to render it very difficult to imagine that the observed chilling can be ascribed to contact with water, the agent responsible for surface chilling in the case of pillow lavas. In most respects, however, the descriptions given have been confirmed. Thus Fig. 2 is a microphotograph of a specimen collected at the most representative 'pillow' locality, and illustrates a contact of chilled basalt against granophyre, the former merging outside the field of view into dolerite. Two things are abundantly clear: (1) progressive reduction of basaltic texture towards the contact; and (2) crystallization of the granophyre against the contact, as indicated by arrangement of marginal growths of hornblende and magnetite. In addition, though the photograph fails to reproduce it, the slide itself reveals under the microscope positive evidence of contact-alteration of the chilled basalt.

As a straightforward interpretation it is claimed that basic magma has risen into contact with acid magma, and has cooled sufficiently against it to develop within itself a marginal, interliquid crust. This, on its basic side, has continuously grown with at first increasing coarseness of grain; while on its other side, it has, after some delay, furnished attachment for crystallization from the acid magma, slightly contaminated. In such circumstances, it is understandable that the chilled basaltic crust, held for a long time above the crystallization temperature of adjacent acid magma, should show a certain amount of contact-alteration (annealing).

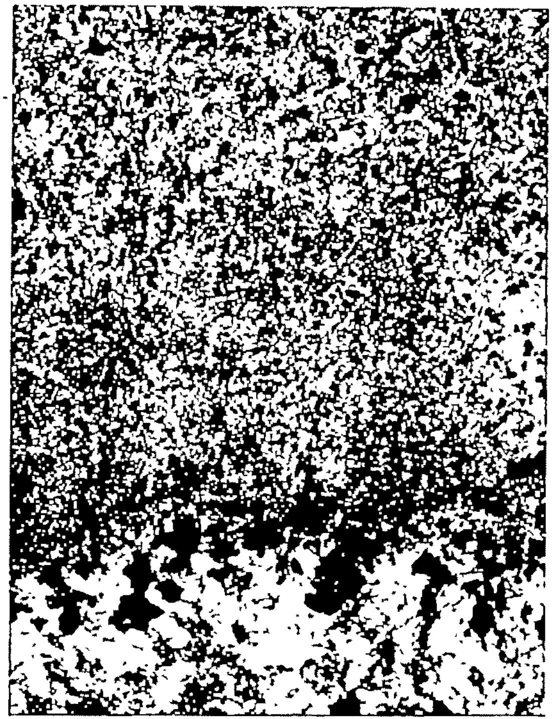

Fig. 2. Contact of chilled subvariolitic basaltic edge of dolerite against granophyre, N.E. side of lane 1 mile 800 yards south (a little west) of Slieve Gullion summit (× 10)

This interpretation is greatly strengthened in that it can be applied without modification to analogous neighbouring exposures where everyone agrees that geometry forbids a pillow-lava hypothesis. Thus we read of "hypersthene-dolerite cut by veins of granophyre", and "yet the hypersthene-dolerite has fine-grained edges resembling chilled edges" (ref. 2, pl. I, 3); and again, in relation to a microphotograph of the result (ref. 2, pl. II, 5)—very like our own Fig. 2 but from a different locality: "The field shows phenocrysts of pyroxene and crystallites of plagioclase in a subvariolitic matrix. The texture of the matrix becomes even finer-grained as the granophyre is approached. A few inches from the contact the hypersthene-dolerite has a grain-size of from ·2 to 1·1 mm."—in contrast to almost nothing near the granophyre. This towards-margin diminution of grain-size is taken by Bailey once again to denote chilling. It is difficult to see how it can be due to remelting, as advocated by Reynolds (ref. 2, pp. 118–122), or yet to metamorphism, Richey's alternative[3].

L. R. Wager

[3] Richey, J. E., *Proc. Geol. Assoc.*, **48**, 274 (1937).

Prof. L. R. Wager and Sir Edward Bailey write: "Evidence from opposite ends of the [British Tertiary] province, 250 miles apart, forced us to postulate chilling and crystallization of basic magma against acid magma". Since, so far as the southern end of the province is concerned, their "evidence" is a re-interpretation of observations made by me at Slieve Gullion, I feel it necessary to point out the incompatibility of the re-interpretation with my published observations[1,2].

At Slieve Gullion a pile of gently dipping layers of dolerites of various compositions and textures is transgressed by plug-like masses, veins and net-veins of granophyre or related types of acid rock. The point of immediate importance is that study of the relationships of the dolerite layers to one another and to the transgressive granophyres revealed the presence of fine-grained edges which cannot all have originated in the same way. Two of the basic layers resemble sills in that they exhibit fine-grained margins at both their upper and lower contacts. The fine-grained edges of sills adjoin pre-existing rocks which were relatively cold when the sills were intruded, and it is for this reason that such fine-grained edges are commonly interpreted as chilled edges.

In the lower part of the pile the dolerite at some localities exhibits pillow structure, the pillow forms, which measure 2–8 ft. in greatest diameter, being bounded by fine-grained selvedges. Pillow structure is a relatively rare geological phenomenon, known only in basic lavas. Knowledge as to its origin is derived from present-day observations that pillow structures form when certain basaltic lavas flow into water, rapid surface chilling accounting for the fine-grained edges of the pillows. Bailey's interpretation of the Slieve Gullion pillow structures as a consequence of basic magma rising into contact with acid magma has no observational background, and is, moreover, inconsistent with the evidence provided by the rocks themselves. His interpretation implies that the fine-grained edges of the pillow structures always adjoin acid rock. This is not the case. Although veins of acid material have commonly been emplaced along the boundaries of the pillows, there are abundant examples of contiguous pillow structures without intervening acid rock. In these examples the fine-grained edges are still present and in juxtaposition with one another. Consistent with my own interpretation of the pillow structures as having originated in the normal way as a consequence of basaltic lava flowing into water is the occasional discovery[1], by crofters, of small pockets of 'coal' within rocks exhibiting pillow structure. The 'coal', which burns well, is possibly carbonized wood derived from trees which, like Macculloch's Tree in Mull, were engulfed in the lava-flows.

As already noted, the dolerite layers are transgressed by plug-like masses, veins and net-veins of granophyre against which the dolerites commonly exhibit fine-grained edges. Since these fine-grained edges in many respects resemble the fine-grained edges of the sills and pillow structures, Bailey supposes them to be edges of masses of basic magma which were chilled against relatively cool acid magma. It is mechanically impossible for acid net-veins to be a result of basic magma rising into acid. Apart from this, it is evident in the field that the plug-like masses and veins of granophyre commonly transgress the lineations of the dolerites. These granophyres and the adjacent fine-grained edges of the dolerite therefore post-date the crystallization of the dolerites. There is, moreover, evidence that these fine-grained margins represent dolerite which had melted at the time of the emplacement of the magma (or other mobile antecedent) of the granophyre. Where granophyre veins transgress dolerite characterized by phenocrysts of bytownite, the fine-grained dolerite edges contain corroded relics of bytownite which are dissected by stringers of pale yellowish glass such as result from partial melting. The refractive index of the glass (1·5331) is consistent with its having a composition An_{55} corresponding to that of the liquid which would form first if the bytownite were fused[3]. By reference to the thermal equilibrium diagram of the plagioclases[3], the temperature at which liquid of composition An_{55} would form from the bytownite concerned is 1,458° C. at atmospheric pressure. Evidence[1] indicates, however, that the melting took place at a water-vapour pressure of the order of 300 bars. The lowering of the fusion temperature of albite in the albite – water system at a vapour pressure of 300 bars is about 103° C.[4]. If the lowering of the fusion temperature of the bytownite concerned, in the presence of water vapour, is of the same order, then the partial fusion of the bytownite may be taken as indicating a minimum temperature of about 1,355° C. At this temperature a high proportion of what is now the fine-grained margin of the dolerite would be melted. From the presence of swallow-tail plagioclases in many of the fine-grained edges, it can be inferred that the melted material mainly solidified as glass which has since devitrified.

These criteria are important not only in demonstrating the origin of the fine-grained edges of the dolerites adjoining transgressive granophyre, but also in providing, so far as I know, the first recorded geological evidence as to the temperature of a granophyre 'magma'. Wager and Bailey make no reference to the paper[2] in which the details of my investigation are recorded, although at a symposium on the origin of gabbro held by the Royal Society of Edinburgh on February 16 of this year, in which they took part, I cited this evidence, with reference to the Campbell volume[2] in which it is published and to which Bailey himself contributed.

So far as the rocks of the Slieve Gullion area are concerned, Wager and Bailey's hypothesis is demonstrably not valid. Apart from the presence of fine-grained edges, the evidence alluded to by Wager from St. Kilda relates to field structures of associated basic and acid rocks, which he states "are believed to have resulted from . . ." and, later, "are interpreted as . . .". This is far from being evidence at all. By using ordinary structural methods, such as were applied to crystalline rocks more than a quarter of a century ago by H. Cloos, it should be possible to demonstrate whether or not the structures observed by Wager are consistent with his interpretations. Wager, however, makes no reference to applied techniques, and provides no criteria by which the adequacy of his hypothesis can be judged. A fine-grained edge is a fact, but the ascription of it to chilling is a hypothesis, and it is by no means a foregone conclusion that every fine-grained edge is a chilled edge.

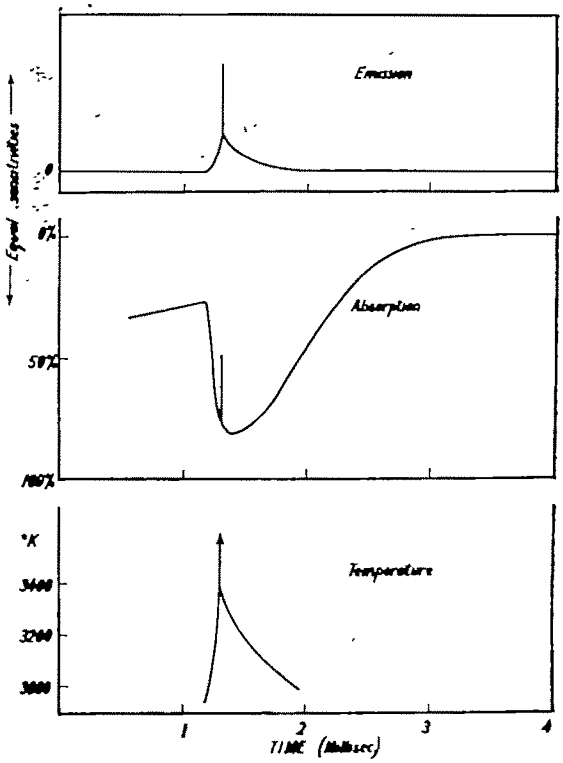
Chemiluminescent Phenomena during Hydrocarbon Combustion

The light emission accompanying the combustion of hydrocarbons in explosions and high-temperature flames has received a great deal of attention and it seems generally agreed that, while normal thermal radiation is present, part of the radiation is non-thermal in origin. Most of the studies have been concerned with radiation which is an integration of light emission over a period of time during which many different stages of reaction and excitation may occur. By means of flash photolysis, we have described how homogeneous initiation of explosions may be brought about and relative radical concentrations measured as a function of time throughout the reaction[1,2]. In order to investigate reversal temperatures and the problem of chemiluminescence, we have now extended our work to the kinetic recording of emission and absorption spectra by photo-electric methods. For this purpose, the spectrograph plate-holder was replaced by a mounting carrying photomultiplier cells behind adjustable slits. The photocell outputs were fed through D.C. amplifiers on to an oscillograph, the overall response-time being about 10^{-6} sec. For absorption measurements the light from a xenon arc was focused first in the centre of the reaction vessel and then on to the spectrograph slit by means of quartz lenses. In these ways it was possible to record very rapid changes in the emission or absorption of selected spectral regions. This has revealed several remarkable features which were not apparent in the earlier work and which have an important bearing on the problem of radiation from combustion processes.

The light emission from homogeneously initiated explosions of acetylene and oxygen containing a small amount of nitrogen dioxide as photosensitizer have been recorded as a function of time in a number of wave-length regions each covering about 40 A. The emission curves in regions where radical spectra are not present, that is, from the continuous spectrum, were similar in shape and duration to the absorption curves of carbon radicals in acetylene-rich mixtures[3]. The emission at wave-lengths corresponding to the spectra of free radicals such as C_2, OH and CN were many times more intense and in addition showed superposed peaks of very short duration. A typical oscillograph record of the latter type, for a fuel-rich system, is shown in the accompanying graphs. It was taken in the region which contains the head of the 0,0 sequence of CN. Near the maximum of the main curve is a superposed peak lasting only a few microseconds, the maximum intensity of which is considerably greater than that of the main emission. Very many examples of this phenomenon have been observed, and although a single peak was generally found in the position shown here, in some cases several peaks were observed during the rise.

The superposed peak seems to be quite separate from the main curve, and the question arises as to whether this implies a sudden rise and decay in the concentration of the radical or a similar rise and decay in the apparent temperature. The problem should be definitely settled by recording the absorption spectrum of the same explosion. This was done in our previous work, but the flash spectroscopic technique had not the time-resolution necessary for such a peak to be detected. The absorption curve now obtained using the same methods of detection as for the emission experiment is plotted below the emission curve in the accompanying figure. It shows quite clearly that the second peak appears in the opposite sense to the main absorption and is therefore a result of an increase in apparent temperature, since an increase in concentration of the radical alone would, of course, result in increased absorption. The peak heights, averaged from a number of records, were the same in emission and absorption, so that, although the effective temperature of the source lamp was 4,070° K., there was no reversal of the peak.



Emission, absorption and temperature of CN as a function of time during an explosion of acetylene, oxygen and nitrogen dioxide at pressures of 14, 10 and 1·5 mm. mercury, respectively

The brightness temperature of the xenon arc at each wave-length was determined by photographic comparison with a calibrated tungsten filament lamp, corrections being applied for light losses at the various interfaces. By combining these temperatures with the curves of emission and absorption, it is possible to obtain measurements of the temperature of the explosion throughout the part showing appreciable emission[4]. These measurements are given in the third trace in the figure, the absolute error over the main curve being estimated as ±100° K. The 'temperature' of the CN radical at the maximum of the superposed peak is probably very much higher than suggested by these experiments, since its emission is only significant over a fraction of the wave-length range used whereas the light-source gives a continuous spectrum over the whole region.

The emission over the main part of the curve probably results from normal thermal excitation. The temperatures, although in excess of the theoretical maximum temperature, are reasonable when the additional heat supplied by the initial flash is taken into account, and this part of the curve is similar in form and duration to those obtained in absorption under the same conditions, indicating that its shape is determined mainly by change in concentration of radical. The superposed peak shows a temperature rise of at least 400° K., and probably very much more than this, in one or two microseconds. These results establish beyond doubt the occurrence of radiation processes which are non-thermal in origin, and which must therefore be classed as chemiluminescent. In particular, they show that such processes appear to be disconnected from the main reaction, do not result in any appreciable permanent change either in temperature or concentration, and occur for only a relatively short period of the whole combustion.

A full account of this work will shortly be submitted for publication in the *Proceedings of the Royal Society.*

Effect of Phenols on the Rate of Decomposition of Benzoyl Peroxide

The decomposition of benzoyl peroxide in solution occurs by unimolecular fission into two radicals:

$$P \rightarrow 2R\text{—}. \tag{1}$$

In 'reactive' solvents (SH) this is accompanied by an induced chain-decomposition[1], namely,

$$R\text{—} + S\text{H} \rightarrow R\text{H} + S\text{—}. \tag{2}$$

$$S\text{—} + P \rightarrow \text{Products} + R\text{—}. \tag{3}$$

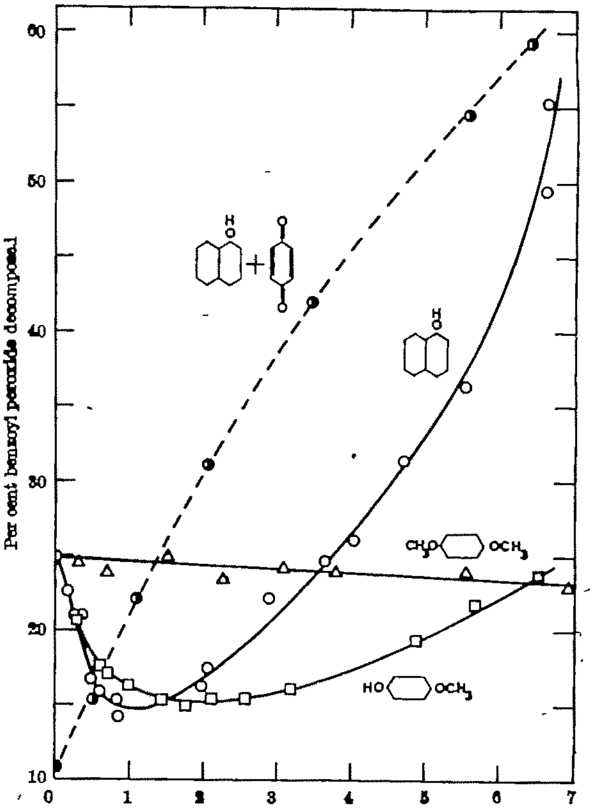
Previous workers have found the induced reaction to be inhibited by quinol[1] and *m*-cresol[2]. On the other hand, when a phenol is used as solvent, it is greatly accelerated[3].

We have examined the effect of increasing concentration of several phenols on the rate of decomposition in various solvents in the absence of oxygen. Results for 1-naphthol and *p*-methoxy phenol (and *p*-dimethoxy benzene) are given in the accompanying graph, in which the percentage peroxide decomposed in 45 min. at 80·65° C. in *cyclo*hexane is plotted against the initial concentration of the phenol. The effect thus depends on the concentration of phenol. Small amounts of phenol inhibit the reaction, but with increasing concentration the rate passes through a minimum and thereafter increases. Similar results were obtained with 2-naphthol and quinol; though with quinol, observation of the minimum was prevented by its low solubility in *cyclo*hexane. The minimum was observed, however, when the decomposition was carried out in dioxane.

Inhibition of free-radical reactions by phenols (FH) is generally ascribed to low reactivity of the radical F—. In the present case, however, the accelerating effect of high phenol concentrations indicates that the reaction:

$$F\text{—} + P \rightarrow \text{Products} + R\text{—} \tag{4}$$

is relatively fast. It is evidently considerably faster than reaction (3). We suggest tentatively that the inhibition of benzoyl peroxide decomposition by phenols is due to the reaction



Fraction (in per cent) of benzoyl peroxide decomposed in 45 min. at 80·65° C. as a function of initial phenol concentration. Initial peroxide concentration in all experiments, 0·017 mol. litre^{-1}. Full curves: 1-naphthol, *p*-methoxy phenol and *p*-dimethoxy benzene in *cyclo*hexane. Dotted curve: 1-naphthol in *cyclo*hexane containing 0·0030 mol. litre^{-1} *p*-benzoquinone. (Results are not corrected for a small residual concentration of *p*-benzoquinone, which interferes with the iodometric peroxide determination; the corrected curve would be a little steeper than that shown)

$$F\text{—} + S\text{—} \rightarrow \text{Inactive products}, \tag{5}$$

F— being derived from

$$R\text{—} + F\text{H} \rightarrow R\text{H} + F\text{—}. \qquad (6)^{2,4}$$

The increase in rate from the minimum thus occurs when sufficient phenol is present to reduce the concentration of S— to a low level. At high phenol concentrations the decomposition then proceeds in the main by the sequence (1) (6) (4). Chain termination probably occurs principally by the reaction

$$F\text{—} + R\text{—} \rightarrow \text{Inactive products}, \tag{7}$$

(7) being slower than (5). (Reaction 7 is required to explain the first-order kinetics of the decomposition in phenol solution[3]; cf. ref. 2.) This explanation is supported by the fact that when the concentration of S— is reduced effectively to zero by adding a sufficient concentration of an inhibitor of a different type (*p*-benzoquinone), the rate progressively rises with increasing phenol concentration (cf. dotted curve in graph). Similar behaviour is shown by quinol and 1-naphthol in the presence of *p*-benzoquinone in dioxane.

The results thus also show that the effect of quinol on the decomposition is not qualitatively different from that of monohydric phenols. Replacement of both hydroxy groups by methoxy groups, however, markedly reduces the reactivity (see graph).

Reaction of Nitric Oxide with Gaseous Hydrocarbon Free Radicals

The inhibiting effect of nitric oxide upon radical chain-reactions in the decomposition of certain organic compounds is well known[1], and such mechanisms as

$$CH_3 + NO \rightarrow CH_3NO \rightarrow H_2CNOH \rightarrow HCN + H_2O$$

have been invoked to explain this inhibition. Although Küchler and Theile[2] obtained traces of cyanide from the nitric oxide-inhibited decomposition of ethane, in no case has the nitroso compound been isolated in such reactions. Coe and Doumani[3] prepared nitrosomethane from the photolysis of *tert.*-butyl nitrite.

As part of a systematic study of decomposition-rates of metal alkyls, we have pyrolysed mercury di-*iso*propyl in a flow system using a carrier gas of nitrogen and nitric oxide. The nitric oxide is rapidly consumed by reaction with *iso*propyl radicals. We have trapped out a yellow solid (presumably 2-nitrosopropane) which melts at about − 85° C. to form a yellow-brown liquid. This liquid speedily changes to a white solid at this temperature. The solid contains both nitroso and oxime groups[4] and exhibits absorption spectra characteristic of acetoxime and a nitroso compound[5]. The ethereal solution is blue, the colour rapidly fading. A series of papers on the reaction of nitric oxide with this and other free alkyl and aryl radicals will be submitted elsewhere for publication.

Proton Acceptor Properties of Deeply Coloured *Cyclo*pentadiene Polymers

*Cyclo*pentadiene can be converted catalytically, by trichloroacetic acid, into a brown-red poly*cyclo*pentadiene – trichloroacetic acid ester, (I), the colour of which is due to conjugated double bonds[1]. If this ester is brought into contact with sufficiently concentrated strong acids, a dark blue, almost black, molecular compound, (II), is immediately formed. In tests in which the concentrations are small, or in which weaker acids are used, the colour of this compound is greenish-blue or green.

The reversible reaction:

$$(I) + (HA) \rightleftharpoons (II) \qquad (1)$$

has now been investigated quantitatively, (*HA*) being the three chloroacetic acids. Hydrochloric, sulphuric and β-naphthalene sulphonic acids were also tested, but were found to be unsuitable for quantitative measurements because the solubilities in appropriate solvents were too low. The equilibrium constant, *K*, of reaction (1) can be represented by the surprisingly simple relationship:

$$K = \frac{[\Sigma x_r]}{[\Sigma(P_r - x_r)]\,[HA]} = \frac{D_{I+II} - D_I}{(D_{II} - D_{I+II})\,[HA]}, \qquad (2)$$

where $[\Sigma x_r]$ and $[\Sigma(P_r - x_r)]$ are the equilibrium concentration of (II) and (I), $[HA]$ is the concentration of the chloroacetic acid (which was always much greater than [I]), D_{I+II} is the optical density of a mixture of (I) and (II), D_{II} is the optical density at an acid concentration sufficiently high to convert all the polymer into (II), and D_I is the optical density in the absence of acid. The validity of equation (2) has been established by many experiments in the concentration-range shown in columns 2 and 3 of the accompanying table, light of 700 mμ being used for the determination of the optical densities. It has also been established at 15°, 20° and 37° and with nitrobenzene as solvent.

Results of Equilibrium and Electrical Conductivity Measurements. Benzene Solution, 25·0°

	Conc. range of equilibrium tests		*K* (l./gm.-mol.)	Conc. range of II in conductivity tests* (10^4 number average gm.-mol./l.)	$\Lambda \times 10^4$ (ohm^{-1} × cm.^{2}/number average gm.-mol.)
	Acid (gm.-mol./l.)	Polymer (10^4 number average gm.-mol./l.)			
Cl_3CCOOH	0·0435–2·44	0·690–8·28	8·1 ± 1	29·2–59·2	7·9–39
$Cl_2HCCOOH$	0·155–6·05	0·828–8·28	0·82 ± 0·18	12·9–30·9	24 – 75
ClH_2CCOOH	0·325–1·56	5·40	0·028 ± 0·006	1·07–2·02	160 – 500

* In these measurements (*HA*) was varied in the range 0·1–1·6 gm.-mol./l. Results of tests at other concentrations will be given elsewhere.

On plotting log *K* (*K* in fourth column of table) against the logarithm of the dissociation constants of the three chloroacetic acids in water, a linear relationship of the Brønsted type holds, which is compatible with the supposition that (I), owing to the π-electrons of the conjugated double bonds, is a proton acceptor[2], and that (II) is a salt. A proton transfer mechanism in the formation of these deeply coloured molecular compounds is consistent with the observation that relatively strong proton acceptors such as piperidine, dioxane, ethyl alcohol or acetone prevent the formation of (II); no such 'inhibition' occurs with polar aprotic solvents, for example, nitrobenzene or chloroform. This mechanism is proved by the marked electrical conductivity of dry benzene solutions containing (II), control experiments having established that the electrical conductivity of a benzene solution containing either (I) or (*HA*) alone is not significant. The 'molar' electrical conductivities, Λ, of (II), relating to the specified concentration-range, are listed in the last column of the table; they are of the same order of magnitude as those of authentic salts in benzene solution[3].

Preparation of Aluminium Tri-Soaps

THE aluminium salts of higher fatty acids find considerable use for various industrial purposes. Their nature and composition are, however, surprisingly obscure. Even the existence of the tri-soaps has been doubted by a number of workers[1], whereas Lawrence[2] believes that tri-soaps of aluminium do exist, and Glazer, McRoberts and Schuman[3] have reported the preparation of aluminium tri-laurate by the reaction between aluminium tri-methyl and lauric acid.

In this communication is described the preparation of the tri-palmitate and tri-stearate of aluminium by the following reaction in the presence of benzene, the *iso*propanol produced being removed azeotropically with the solvent:

$$Al(OPr^i)_3 + 3RCOOH = Al(RCOO)_3 + 3Pr^iOH.$$

1·51 gm. of freshly distilled aluminium *iso*propoxide (1 mole) and 6·30 gm. of double-distilled stearic acid (3 moles) in 80 c.c. of dry benzene were refluxed at a bath temperature of 140–150° C. under a column (60 cm. long filled with Fenske helices) fitted to a total-condensation variable take-off stillhead. 3·6 gm. of distillate was collected in one hour at 72–73° C. and on analysis was found to contain 1·05 gm. of *iso*propanol; 20 gm. of distillate collected between 77° and 80° C. was found to contain about 0·2 gm. of *iso*propanol. Refluxing was continued for another four hours and the distillate was collected at 80° C. under a high reflux ratio (1 : 20). The remaining benzene (about 10 c.c.) was removed by distillation under reduced pressure and the product (a white solid) was heated at 200–220° C. under 0·2 mm. pressure for one hour. The hard white solid thus obtained was analysed: found: Al, 3·09; C, 74·13; H, 12·02 per cent. Al(stearate)$_3$ requires Al, 3·07; C, 73 92; H, 12·07 per cent.

Aluminium tri-palmitate prepared by a similar procedure was a slightly yellow solid which on analysis gave Al, 3·42; C, 72·64; H, 11·90 per cent; Al(palmitate)$_3$ requires Al, 3·40; C, 72·68; H, 11·81 per cent.

The method of preparation appears to be a general one and has been extended to the soaps of titanium and zirconium. Further work on the physical characteristics of these soaps is planned to establish their constitution.

The carbon and hydrogen analyses were carried out by Messrs. Weiler and Strauss, Oxford.

These investigations were carried out at Birkbeck College, University of London. I am grateful to Prof. W. Wardlaw and Dr. D. C. Bradley for their interest and encouragement and to the British Council for a fellowship.

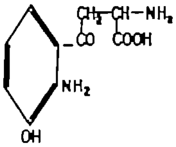
A Possible Common Biogenetic Origin of the Nicotine, Tropane and Hygrine Bases

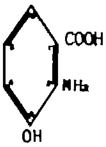
THE isolation of both hyoscine and nicotine from a genotype of *Duboisia myoporoides*[1] suggests the possibility of a close biosynthetic relation between these bases, and is consequently of interest in connexion with the classical schemes of alkaloid biogenesis[2]. However, a synthesis of nicotine or a related compound under so-called physiological conditions has not yet been effected, and it seems desirable to consider a possible alternative mechanism.

Since the publication of a review by R. F. Dawson[3] on alkaloid biogenesis, the metabolic pathway to nicotinic acid from tryptophane has become better known, and evidence that the conversion proceeds by way of the intermediates kynurenine, 3-hydroxykynurenine (I), and 3-hydroxyanthranilic acid (II) is accumulating[4]. It would now seem feasible that the simple 3-substituted pyridine derivatives trigonelline, ricinine and the areca nut alkaloids may likewise be products of this mode of tryptophane metabolism, and result from 3-hydroxyanthranilic acid, which itself occurs in the form of the methyl ester of its O,N-dimethyl derivative as the alkaloid damascenine. In nicotine and related bases, the pyridine ring may have a similar origin, arising by cleavage of the benzene ring in (I) or (II), followed by recyclization. The pyrrolidine ring of *nor*-nicotine could be built up from all or part of the carbon chain already present in (I), or by condensation of (II) or a metabolite of (II) with, for example, acetic acid and glycine, followed by decarboxylation. Such an origin permits the formation of both D_g and L_g *nor*-nicotine; both isomers are found, *nor*-nicotine in *Nicotiana* spp.[5,6] being mainly of the L_g form but the D_g isomer predominating in *D. hopwoodii*[6-8]. The occurrence of both isomers would suggest that the pyrrolidine ring does not arise directly from L_g proline[9]. Apparently nicotine occurs in the L_g form only, even in *D. hopwoodii*[6,8,10]. This is possibly due to failure of biological methylation to take place with D_g *nor*-nicotine.

This speculation receives added interest from the fact that cleavage of the benzenoid ring of (II) between C_1 and C_2 would lead to a C_7N intermediate such as (III), which, on appropriate cyclization, would give rise to the *nor*-tropanone skeleton (IV). The oxygen atoms in (III) are suitably placed to accommodate the naturally occurring oxygenated tropanes. In dihydroxytropane and valeroidine, the oxygen on C_6 is retained as a hydroxy group; in hyoscine it is present in an epoxide ring; in meteloidine the epoxide ring, probably of the diastereoisomer of hyoscine, is opened to form the *cis*-glycol. In addition, the side-chains in ecgonine and dioscorine are accounted for as being possibly derived from the side-chain of (I).



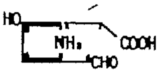
(I)



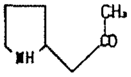
(II)

(III)

(IV)



(V)



(VI)

An alternative carbon chain (V), from which the *nor*-tropanone structure could conceivably be derived, would be obtained by cleavage of the benzenoid ring of (II) between C_6 and C_1.

In *Erythroxylon truxillense*, tropane bases are accompanied by hygrine, and both types of alkaloids are found in the genus *Convolvulus*[11]. Also hyoscyamine and cuskhygrine are reported to occur together in *Scopolia lurida*. These co-occurrences likewise are probably of biogenetic significance, and the hypothetical intermediate (III), which serves above as a source of the tropane structure, could also give rise to the *nor*-hygrine structure (VI) by the appropriate cyclization. The longer carbon chain of cuskhygrine is difficult to account for by this hypothesis. It may be that the plant contains an enzyme system by which hygrine or a precursor is condensed with a compound such as 4-methylaminobutanal.

I wish to thank Dr. J. R. Price and Dr. C. C. J. Culvenor for advice and criticism.

Action of Ninhydrin on Keratin

ALTHOUGH ninhydrin has long been used as a sensitive reagent for the detection of amino-acids, its remarkable cross-linking action on protein fibres appears to be unknown. In the case of wool keratin, the reaction, the extent of which is independent of *p*H between *p*H 4·8 and 8·3, takes place slowly at ordinary temperatures and is incomplete in 48 hr. With a boiling 0·0685 *M* solution at *p*H 4·8, however, cross-linking proceeds so rapidly that after treatment for 15 min. the fibres show a 25·8 per cent increase in resistance to extension (30 per cent) in water at 22·2° C. Since the extent of reaction is reduced when the lysine side-chains are blocked by means of 1-fluoro-2 : 4-dinitrobenzene or nitrosobenzene, and since no strengthening is obtained with completely deaminated fibres, the basic side-chains of keratin must play a fundamental part in the cross-linking reaction.

Besides being capable of strengthening intact fibres, ninhydrin is even more effective with damaged fibres. When, for example, wool fibres were treated with thioglycollic acid until their resistance to extension in water at 22·2° C. was reduced 23·9 per cent, subsequent treatment with the boiling solution of ninhydrin for 15 min. gave fibres the resistance of which to extension was 21·9 per cent greater than that of untreated fibres.

Ninhydrin is thus by far the most effective cross-linking agent so far discovered for keratin, and there is every reason to expect that related compounds, which give uncoloured derivatives, will find extended use in processes for reinforcing protein synthetic fibres as well as natural fibres.

We are indebted to the International Wool Secretariat for grants in aid of this investigation.

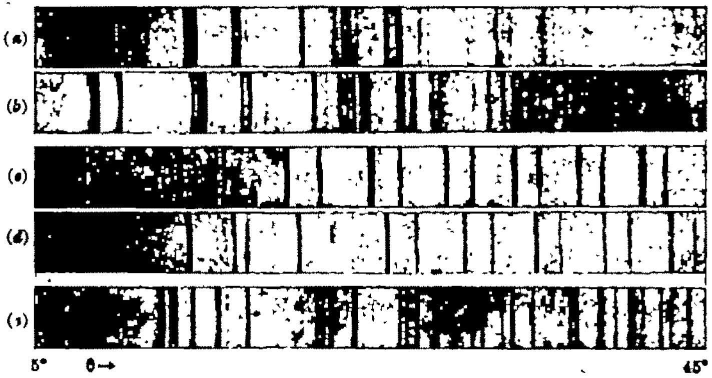
Alkaline Earth Uranates of the R_3MX_6 Type

ALKALINE earth uranates of the RMX_4 type are well known and the crystal structures of, for example, the calcium and strontium compounds $CaUO_4$ and $SrUO_4$, respectively, have been investigated in detail[1].

While studying phosphors of the CaO(U) type, it was decided to investigate the formation of other possible uranate compounds. A range of samples containing varying ratios of calcium to uranium was prepared and a transition in fluorescence properties was observed at a 3 : 1 ratio. It was suspected that a calcium compound having the composition 3CaO : $1UO_3$ had been prepared, and an X-ray investigation showed the existence of a new compound. Other similar uranates were prepared and it was found that the new materials possessed the same pseudo-cubic crystal structure as alkaline earth tungstates of the R_3WO_6 type[2], and fluorides of the cryolite, Na_3AlF_6, type[3].

The above tungstates and fluorides approach and attain full cubic symmetry (space group *Fm3m*) when ionic dimensions are favourable. The ideal structure involves cations occupying two different sites with relative abundance of 2 : 1. For this reason, and because ionic radii are favourable, Ba_2CaWO_6 possesses the full symmetry of the *Fm3m* cubic space group. With this in mind, the further uranate Ba_2CaUO_6 was prepared. The X-ray powder photograph, while revealing slight deformation from the fully cubic arrangement, owing no doubt to the difference in volume between the UO_6 group and the WO_6 group, confirmed that the uranates follow the same general behaviour as the corresponding tungstates.

To check the isomorphism of the tungstate and uranate systems, the intermediate compound $Ca_3(0{\cdot}5W\ 0{\cdot}5U)O_6$ was prepared. The resulting material was found to be a complete solid solution and to possess a pseudo-cubic structure cell dimension of $a_0 = 8{\cdot}1_6$ A., compared with $8{\cdot}0_5$ A. for Ca_3WO_6 and $8{\cdot}2_6$ A. for Ca_3UO_6. X-ray powder photographs of Ca_3UO_6, Ba_2CaUO_6 and, for comparison purposes, $CaUO_4$, Ca_3WO_6 and Ba_2CaWO_6, are reproduced herewith.



X-ray powder photographs of: (a) Ca_3UO_6; (b) Ca_3WO_6; (c) Ba_2CaUO_6; (d) Ba_2CaWO_6; (e) $CaUO_4$. 19-cm. diameter camera; copper $K\alpha$ radiation

Synthesis of the various compounds was accomplished as follows. Using appropriate molecular proportions, alkaline earth carbonate was made into a paste with uranyl nitrate solution; where necessary, tungstic oxide was mixed with the carbonate. The resultant paste was dried at 250° C. and fired for one hour at a temperature in the range 1,150–1,350° C., according to which compound was being prepared. The R_3MX_6-type uranates are pale-yellow in appearance.

In common with other uranium compounds, the fluorescence spectra show many interesting features. For example, at liquid-air temperature the fluorescence of Ca_3UO_6 under long wave-length ultra-violet radiation is yellow-green and of medium intensity. The emission consists of a continuous band with a superimposed set of lines or sharp bands, whereas at room temperatures there is a weak diffuse green fluorescence.

Different spectra, but of the same general type, are obtained with the other uranates such as Ba_2CaUO_6. When activated with samarium or europium, these phosphors show, especially at low temperatures, a strong fluorescence exhibiting the characteristic line spectrum of the particular rare-earth activator. With samarium a predominantly orange fluorescence is obtained and with europium the fluorescence is orange-red.

It is hoped to publish a fuller account of the fluorescent properties of these uranates and of related phosphors at a later date.

Irradiation of Polymers by High-Energy Electrons

THE interaction of high-energy radiation with various forms of matter has been shown to produce a variety of chemical effects, depending upon the system. These effects fall into various classes, among which are oxidation and reduction, polymerization and depolymerization. Recently, Charlesby and Little have reported the cross-linking of polymers by high-energy radiation[1-3].

Our work in this field has been with high-energy electrons, such as are produced by a resonant transformer-type cathode ray equipment, which supplied electrons having peak energy of 800 kV.[4]. We have covered a dose-range from below one million to several hundred million röntgen units. Most of the work which Charlesby[1,2] has reported to date has been with radiation from an atomic pile, although Little[3] has made a study of the crystallinity of polymers irradiated by electrons from a Van de Graaff generator.

We have made measurements of solubility, swelling, gas evolution and physical properties on a large number of polymers irradiated with our equipment. These polymers fall into two classes: those that become degraded and those that become cross-linked. The accompanying table lists some of the polymers investigated.

Polymers becoming cross-linked	Polymers becoming degraded
Polyacrylic esters	Polymethyl methacrylate
Polystyrene	Polyvinyl chloride
Polyesters	Polyvinylidene chloride
Nylon	Polytetrafluoroethylene
Polyethylene	Polychlorotrifluoroethylene
Chlorinated polyethylene	Cellulose
Chlorosulphonated polyethylene	Polyisobutylene
Natural rubber	
GRS	
Butadiene-acrylonitrile copolymers	
Neoprene-W	
Neoprene-GN	
Polydimethylsiloxanes	
Styrene-acrylonitrile copolymers	

A number of other polymer mixtures, co-polymers, and polymer–monomer mixtures have also been found to become cross-linked as a result of irradiation. Although the mechanism of the process is not well established in each of the above examples, some general statements covering possible mechanisms can be made. These, however, will be reserved for future publications.

The polymers that were found to become cross-linked appeared to behave as would be generally expected for a cross-linked material. They were no longer soluble in solvents for the unirradiated material; they showed improved form-stability at elevated temperatures; the tensile strength and ultimate elongation changed upon irradiation; and they for the most part changed from plastic to elastic substances.

We have investigated the properties of polyethylene, nylon and polydimethylsiloxane in some detail. During the irradiation of polyethylene, hydrogen was evolved in a quantity found to be proportional to the amount of irradiation. These results have been compared with our solubility and swelling results, analysed by the methods of Flory[5] and Flory and Rehner[6], and indicate that the number of cross-links was also proportional to the amount of irradiation. Hydrocarbon compounds up to C_{11} were evolved during the process. Definite changes in the infra-red spectrum have been noted. The optical density at 5·8 μ was approximately proportional to the amount of irradiation.

Polyethylene samples covering the range of reported molecular weights from 2,100 to 24,000 have been irradiated. The amount of irradiation necessary to cause insolubility was found to vary inversely as the 1·26 power of the molecular weight. A sample of paraffin wax required the high dose of 800–900 million röntgen units to convert it into an insoluble rubber-like material. This is approximately the dose predicted from the extrapolation of the above molecular weight – solubility studies.

The effects of temperature and rate of irradiation have been investigated. No change in cross-linking efficiency, as determined by swelling measurements, could be observed over the range of irradiation temperatures from − 74° C. to + 193° C. Likewise, no differences could be observed between samples which had been irradiated with 30 million röntgen units during 1 min. or 30 min. Apparently this process is somewhat different from the free radical polymerizations reported earlier[7], where the results were sensitive to dose-rate and temperature.

Both the tensile strength and the ultimate elongation of polyethylene showed an initial increase with irradiation followed by a slow decrease at high doses. The rate of decrease for ultimate elongation, however, was greater than it was for tensile strength. The initial improvement in both was more marked for the lower molecular weight samples.

The nylon and polydimethylsiloxane samples behaved somewhat similarly to polyethylene. Again the amount of cross-linking appeared to be proportional to the amount of irradiation, the physical properties changed, and the solubility was affected. The efficiencies for cross-linking varied widely from polymer to polymer.

Electrical Properties of Chromium Oxide – Alumina Catalysts

Some examples of relations between the activity and the electrical conductivity of catalyst surfaces have been described, notably by Garner, Gray and Stone[1] for copper and copper oxide films. Measurements with a similar degree of accuracy have not been recorded for precipitated catalysts. Experiments with mixed molybdenum oxide – silica (MoO_3–SiO_2) catalysts, in this laboratory, were discontinued because of the unavoidable presence of metallic molybdenum in such preparations[2].

We have now investigated the electrical conductivity and thermoelectric potential of coprecipitated chromium oxide – alumina (Cr_2O_3–Al_2O_3) catalysts. The test specimens take the form of a small disk 1 mm. thick and 9·5 mm. in diameter, made by compression of the catalyst into a glass cell after reduction of the finely powdered solid in hydrogen and without exposure to air. Contacts are made by platinum disks welded to platinum wires, and small thermocouples are attached to each face. The conductivity is measured by determining the residual charge in a condenser after leakage through the specimen for a known time. The thermoelectric potential is measured by charging a small condenser from the heated specimen, and then discharging it through a ballistic galvanometer.

Results for conductivity of 70 per cent chromium oxide – 30 per cent alumina after reduction in hydrogen at 500° for 50 hr. followed by evacuation were fully reversible in the range 200°–500°, and satisfied equations of the type $\sigma = A \exp(-\varepsilon/KT)$. On plotting log σ against $1/T$, two intersecting straight lines resulted, as shown in Fig. 1. The conductivity increased in hydrogen, and also when the sample was heated at 500° in oxygen; the oxide may therefore be termed an amphoteric semi-conductor. The thermoelectric potential of the catalyst after reduction in hydrogen varied, as shown in Fig. 2, the hot face being positive. It is clear that the oxide is an electron-excess semi-conductor, unlike chromium oxide in its normal state[3]. This is not in accordance with earlier statements on chromium oxide after treatment with hydrogen. Specimens of the catalyst heated in air at 500° show a reversal of potential.

One fully reduced specimen, exposed to air after cooling to room temperature, but reheated in hydrogen after packing into a cell, was used for determination of the Hall coefficient by the Telecommunications Research Establishment, Great Malvern, using an alternating magnetic field at 50 c./s. and a primary

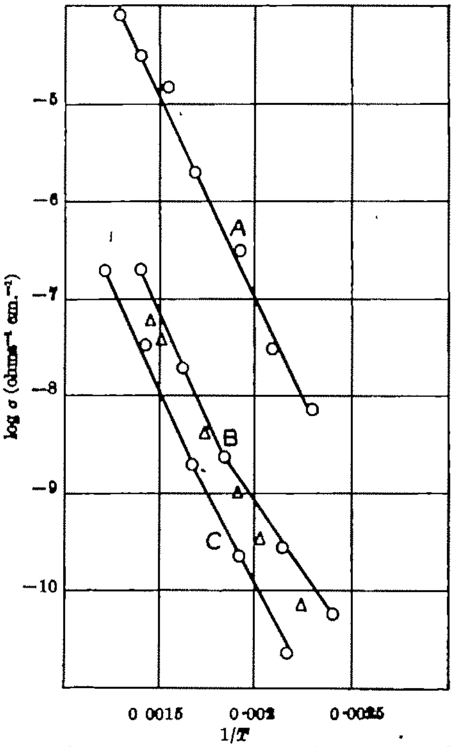

Fig. 1. *A*, in oxygen; *B*, in hydrogen (Δ, second specimen); *C*, in vacuum

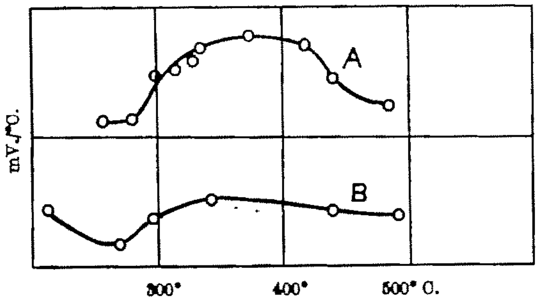

Fig. 2. *A*, in hydrogen; *B*, in oxygen

current at 60 c./s., and measuring the induced 10 c./s. current. This gave a value of 1·77 × 10^{5} cm.^{3}/coulomb for the coefficient of an electron-excess semi-conductor at 442°. The conductivity of this specimen was 1·1 × 10^{-3} ohm^{-1} cm.$^{-1}$. We are greatly indebted to Mr. D. A. H. Brown for his interest and participation in these measurements.

These preliminary results indicate that such methods for examining mixed catalysts offer considerable promise, but that great care is essential in the preparation and handling of specimens. In the present series, the semi-conducting properties begin to be measurable in the same temperature-range as the activity for dehydrogenation of heptane and for chemisorption of hydrogen on the clean catalyst. It therefore seems possible that the centres concerned in chemisorption are the same as those responsible for electrical conductivity. If this were so, the activation energies for the two processes should be closely related, and measurements are being continued to investigate this point.

A Resistance-Network Analogue Method for solving Plane Stress Problems

PLANE stress problems can be described by the Airy stress function χ, which satisfies the biharmonic equation

$$\nabla^4 \chi = 0, \tag{1}$$

the stress components being the second derivatives of this function. A resistance network method has been developed which solves the biharmonic equation.

As has been shown by several authors[1-3], a network of interconnected resistances solves the second-order partial differential equation

$$\nabla^2 \chi(x,y) = \Phi(x,y), \tag{2}$$

the function $\Phi(x,y)$ representing the current fed into the network node (x,y). Now suppose that $\Phi(x,y)$ is the solution of a second-order differential equation,

$$\nabla^2 \Phi(x,y) = f(x,y), \tag{3}$$

where $f(x,y)$ is a known function of the co-ordinate x and y. Then obviously

$$\nabla^4 \chi(x,y) = f(x,y). \tag{4}$$

To establish the solution of equation (4), one need only connect two identical resistance networks in cascade by joining corresponding nodes in the two networks by (relatively) high-value series resistances, and feed in currents at the 'upper' network corresponding to $f(x,y)$, while applying the boundary conditions appropriate to $\Phi(x,y)$ at the 'upper' network. The voltages $\Phi(x,y)$ then appearing in the 'upper' network, and representing the 'solution' of equation (3), constitute the sources for the currents fed into the 'lower' network, the currents being proportional to these voltages. Hence, equation (4) is satisfied by this network arrangement. This principle might be extended to the solution of partial differential equations of higher even orders, but practical difficulties arise through the potential division in the network cascades, and the ensuing low signal-level in the 'lowest' network. This particular difficulty makes itself already felt in the network cascade to solve the biharmonic equations (1) or (4), because relatively high accuracy in the determination of the χ function (a few parts in 10,000) is required, in order that the stress components can be obtained with an accuracy of 1–2 per cent by numerical differentiation of the measured $\chi(x,y)$ values. However, this accuracy has now been achieved in an experimental apparatus set up to test the practicability of the method.

Another difficulty is that usually unfavourable boundary conditions are specified, for example, χ_B and $(\partial\chi/\partial n)_B$, which correspond to the case of 'ill-conditioning' in numerical methods of solving equation (1)[4]. This has been overcome by setting up one of the boundary conditions, for example, $(\partial\chi/\partial n)_B$, and displaying (on a cathode ray oscillograph screen) the other one, χ_B, simultaneously for all boundary points. The boundary values of the Φ function (at the 'upper' network) are then adjusted until the observed χ_B values have their prescribed values within specified limits. This mode of operation is, to some extent, the experimental counterpart of Southwell's relaxation method[5], but the networks are 'self-relaxing' in their interior[3], and the error signals along the boundaries are all simultaneously in view. Hence, although the problem is 'ill-conditioned', a solution of sufficiently high accuracy can usually be established in a relatively short time; for example, present experience has shown that in a typical case, with a total of about 250 mesh points, and twenty-five displayed boundary points (the other boundary points having fixed boundary values), the solution can be established in less than half an hour to within 3 parts in 10,000. Of course, the extraction of the full information and the evaluation of the stresses at all mesh points takes much longer.

A more detailed account of the method and its experimental realization will be published elsewhere.

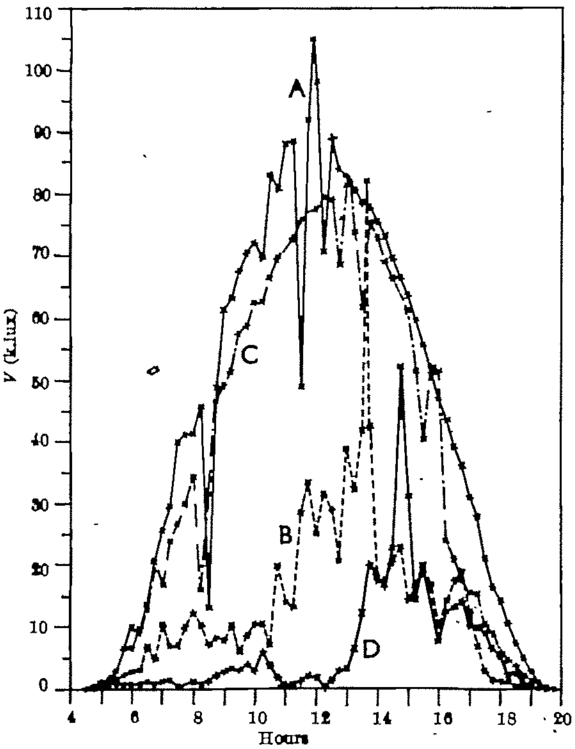
Reduction in Light accompanying Exceptionally Heavy Rain

We are indebted to Prof. J. H. J. Poole for the suggestion that our record of illumination during very heavy rain last August might be worth studying further. We accordingly compared the data for sunshine, rainfall until 3 p.m., maximum vertical illumination in kilolux and the illumination integral in kilolux-hours for four days: August 10, clear and sunny; August 11, completely overcast sky until about 11 a.m. G.M.T.; August 14, clear and sunny; and August 15, exceptionally dark and wet until about 1 p.m. The Lynmouth flood was occasioned by the rain of August 15, falling rather later in that district.

The accompanying graph shows kilolux plotted against time, based on measurement of the charts, obtained with a Burt vacuum sodium cell and Cambridge thread recorder[1]; for reproduction the minute-by-minute dots were replaced by quarter-hour readings, but in addition maxima and minima were included. The original chart, with current shunted to 0·2 for summer use, could be read to 0·1 scale division, corresponding to 0·35 kilolux, approximately half the vertical illumination immediately before the first appearance of the sun's disk at sunrise. One's visual impression was that at the minima, 11 a.m. and at 12.15 p.m. on August 15, the illumination was much below this; in a south window, reading was possible but not comfortable.

The high values of V maximum, even on the overcast days, were due to momentary clearings in the afternoon, though the Plymouth Hoe sunshine card showed no sun on August 11 and 15.

It has been shown[2] that considerable thicknesses of unbroken high cloud may still allow an apparent percentage transmission of 35–40, though 1,000–2,000 ft. of low stratus may cut the light to 20–35 per cent around noon. But lofty cumulus or cumulonimbus cloud, with tops emergent above the total cover of the lower layers, may reduce the apparent percentage transmission to between 6 and 12 per cent if their bases are low. Unrecorded thicknesses in thunderstorms have reduced transmission to about 1 per cent. The thick cloud on August 11 reduced transmission to 8 per cent about 10.30 a.m., but on August 15 it sank at times to 0·5 per cent or less, and the integrated illumination 13 k.lux-hr. up to 1 p.m. was approximately 4·5 per cent of that for a clear day up to noon. The darkest day we have on record was November 29, 1934, which drizzled to about 0·7 k.lux at 11 a.m. and for the whole day had 14·5 k.lux-hr.



The ordinates show the vertical component of the illumination from sun and sky, in kilolux. The abscissae show time of day. Curves *A*, August 10; *B*, August 11; *C*, August 14; *D*, August 15

PLYMOUTH HOE OBSERVATIONS

1952	Sun (hr.)	Rain (mm.)	V max. (k.lux)	K.lux-hr.	K.lux-hr. 4.45 until
Aug. 10	11·12	0	105	630	
11	0·0	4	82	198	39 (10.30)
14	9·12	0	82	582	
15	0·0	82	52	96	13 (13.00)

Since most of the water in the towering clouds indicated by the very heavy reduction in daylight must have come in from the Atlantic with relatively little smoke pollution, it is probable that reflexion from the sides and the exit from the column of scattered sunlight accounts for by far the greater part of the loss of light. Such a loss of scattered light could not occur where the sun's rays fall on a level surface of cloud.

Albumin: an Unsuspected Physiological Activity

When testing various fractions of human blood plasma prepared by ether precipitation in the cold[1], it was found that albumin had a definite effect on the perfused rabbit's heart. In view of this, and the fact that albumin has been used for clinical transfusion for some years without any evidence of ill effect, the reaction has been studied in some detail.

Both albumin issued for clinical use (96 per cent pure) and albumin of 100 per cent purity as established by electrophoretic and ultra-centrifugal measurements have been used. If a dose of 0·3–0·5 ml. of a 3–6 per cent solution of albumin in saline (pH 7·2) is introduced into the Ringer–Locke solution proximal to the cannula of a Langendorff rabbit-heart preparation, the following is observed. The amplitude of the ventricular beat is immediately considerably reduced; this may, or may not, be accompanied by a slowing of the heart. The coronary flow is definitely increased for a short time and is then sometimes decreased. With a dose of 0·3 ml. of 3 per cent 'pure albumin', the duration of the whole effect is about thirty seconds, after which time both the beat and the coronary flow have returned to pre-injection levels. Full atropinization does not affect the result. The change in coronary flow is not due to the alteration in heart beat, for a similar change occurs in the fibrillating heart. There is no alteration in the electrocardiogram. The changes are not due to an osmotic effect, a slight diminution of amplitude and a slowing in coronary flow being observed after the injection of 0·5 ml. of 6 per cent 'Dextran' saline.

Similar effects are observed in the perfused guinea pig's heart, but no change occurs in the beat of the intact guinea pig's heart when the albumin is injected directly into the left auricle[2], even when 0·5 ml. of 16 per cent pure albumin solution is rapidly injected. Albumin has also been injected into the auricle of animals which have been repeatedly bled and the loss made good by the transfusion of 'Dextran'; 0·5 ml. of 12 per cent pure albumin is without effect when the hæmatocrit has fallen to a value of 10 per cent red cells. As would be expected, there is no immediate change in carotid blood pressure when the albumin is rapidly injected into the jugular vein of the intact or bled guinea pig in which the loss has been made good with 'Dextran,' the result being a gradual rise in blood pressure.

In the method of intra-auricular injection, the dose floods the left side of the heart and passes rapidly through the coronary arteries, and the reason why the albumin is without effect even in large doses is not understood. If the albumin fraction is dialysed against several changes of saline or water, it is still active though on a somewhat reduced scale. A similar effect is seen with human albumin prepared by the Cohn's ethanol[3] precipitation, and with albumin prepared from horse, sheep, ox and rabbit blood by ether–alcohol precipitation.

The fact that albumin prepared from rabbit's blood affects the perfused rabbit's heart in the same way as albumin prepared from other species indicates that it is not a foreign protein effect. The lipoproteins and the gamma globulins are devoid of this particular activity.

The action of albumin upon the isolated rabbit's or the guinea pig's gut is variable. On some occasions there is an abrupt relaxation, while on others there is a constrictor effect, or there is little or no effect. In the perfused rabbit's ear, an injection of 0·5 c.c. is followed by an increase in flow.

The physiological effects observed are consistently associated with albumin, but the criteria of purity does not preclude the possibility that they are in fact due to some smaller molecule associated with it.

From these experiments it would seem extremely unlikely that the reaction seen is of any practical significance in blood transfusion, where the introduction of albumin is much slower. This is borne out by the absence of any clinical ill effect, even where albumin is transfused rapidly as a 25 per cent solution. The use of albumin experimentally, however, might well show up effects which would fall into line with our results.

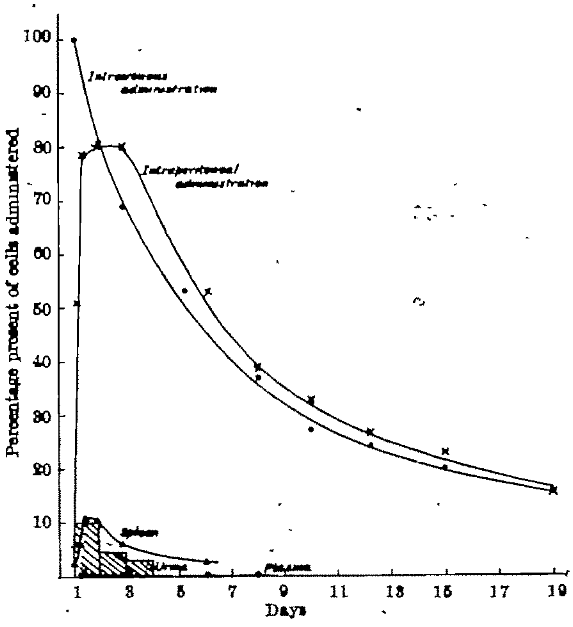
Studies with Erythrocytes labelled with Radioactive *p*-Iodophenylhydroxylamine

A technique has been developed in this laboratory for the rapid labelling of erythrocytes *in vivo* and *in vitro* using *p*-iodophenylhydroxylamine ($I.C_6H_4.NH.OH$) containing radioactive iodine. This compound, together with its green oxidation product *p*-iodonitrosobenzene ($I.C_6H_4.NO$), has a remarkable affinity for hæmoglobin, and in spite of its insolubility in water rapidly penetrates red cells and combines firmly and stoichiometrically with the cell pigment[1]. The reaction with hæmoglobin and some of its derivatives has been examined in detail and appears to be irreversible so long as the hæm molecule remains intact.

The facility with which the process may be applied to cells has made possible a detailed study of the rate of turnover of erythrocytes in several mammals (rat, mouse and dog) and in hens; it should be applicable to all animals possessing hæmoglobinated corpuscles. During the course of this work when the validity of the technique was being established, it was found that labelled red cells were rapidly absorbed from the peritoneal cavity of the rat, and this observation has since been extended to the mouse and dog. In the rat, in which the most detailed studies have so far been made, it has been shown that the cells retain the viability of the same cells administered intravenously (see graph).

In this experiment about 10 per cent of the radioactivity administered as cells by the intraperitoneal route appeared in the urine within 24 hr., and a similar quantity of activity was found in the spleen. It must be emphasized, however, that the amount of iodophenylhydroxylamine associated with the cell in this case had to be great enough to enable the disappearance of cells from the blood to be followed for an adequate period of time, limited as it is by the relatively short half-life of the radioactive



Comparison of the fate of red cells labelled with radioactive *p*-iodophenylhydroxylamine after intraperitoneal and intravenous administration to rats. Each point represents the mean result for five animals (200 gm. weight) after the same dose of cell suspension (= 0·5 ml. blood per animal; label equivalent to 90 μgm *p*-iodophenylhydroxylamine/ml. cell suspension) iodine. The magnitude of the cell label has an important influence on the survival-time of the cells.

Full reports on the various aspects of this work will be published elsewhere; meanwhile the mechanism of absorption of cells from the peritoneal cavity and the application of this technique to the human subject are being investigated.

'Sex-Ratio': a Non-Mendelian Character in *Drosophila bifasciata*

On three independent occasions an exceptional trait has been recovered in collections from Nature of females of *D. bifasciata*: in Pavia in 1943 [1] and 1947, and in Mergozzo (Lago Maggiore) in 1947. This trait expresses itself in an abnormal sex-ratio of offspring from females mated to any type of male. By analogy with previously described cases[2], the character has been designated as 'sex-ratio'. The strain used in the experiments discussed here originated from the 1947 collection in Pavia. The behaviour of this stock can be summarized as follows.

(1) Sex-ratio females produce on an average only 0·5 per cent males, while normal females produce about 47 per cent males. The sex-ratio strain can be maintained only by crossing any females originating from sex-ratio mothers with normal males of the same species. The source of the flies used as male parents has no effect on the transmission of the abnormal sex-ratio, as shown by tests of five geographically different strains (including one of Japanese origin).

(2) The percentage of males has not varied significantly throughout five years with two important exceptions, noted below, when it was raised ten-fold.

(3) The trait is transmitted only by females (and by all of them) originating from the cross sex-ratio ♀♀ × normal ♂♂, and not by any of the rare male offspring of such a cross.

(4) Only somewhat less than half the eggs laid by sex-ratio females hatch.

The more obvious genetic explanations of the exceptional behaviour may be readily ruled out. Thus spontaneous parthenogenesis is excluded by the fact that the eggs laid by virgin sex-ratio females are infertile. Parthenogenesis induced by sperm or copulation is similarly excluded because it can be shown that in crosses between sex-ratio females and normal males with suitable markers (including a sex-linked one) the male genotype contributes to the genotype of the offspring in a regular fashion. Explanations resting on sex-linked lethals, attached *X*-chromosomes, and non-disjunction phenomena or chromosome aberrations can be ruled out by the fact that the above-described transmission of the trait has persisted unchanged for more than eighty-one generations, produced by mating the females of the line with normal unrelated males. It thus seems that the genetic basis of this character is of extra-chromosomal nature.

The unusual determination of the trait is further demonstrated by the fact that sex-ratio females laying eggs at the raised temperature of 26° C. produce an approximately normal sex-ratio among their offspring. This thermal 'cure', however, is not permanent, since when such females are returned to the normal temperature of 21° C., they revert to their original behaviour, that is, their eggs containing putative males fail to hatch. The temperature at which the male mates of the sex-ratio females under heat treatment have been reared has no effect on the sex-ratios produced. Furthermore, temperature treatment of virgin sex-ratio females is ineffective. It seems that the effect of the heat treatment is exercised in the time interval between the last hours of maturation of the eggs and the first 12–18 hours of zygote development. It is worthy of note that the two 'cases' of spontaneous 'cures' mentioned above occurred when the room temperature at which the flies were kept rose suddenly to about 25° C. (once in the summer of 1951 and once in March 1952).

The offspring of temperature-cured sex-ratio mothers differed in their behaviour according to treatment. Those originating from zygotes kept at 26° C. only prior to pupation produced 17–19 per cent males in their progeny, irrespective of the length of the treatment (1–12 days). Those kept at 26° C. until after emergence produced 39 per cent males. It would thus appear that a second temperature-sensitive period exists during the pupal stage.

These results were obtained from mass cultures. Experiments on single fly cultures from treated females showed that the percentage figures quoted resulted from variable behaviour of individual females: some produced normal sex-ratios, some behaved in the manner typical for the sex-ratio strain, and others gave intermediate results. Granddaughters of treated females continued to segregate, that is, normal, intermediate and sex-ratio females were recovered from all three categories. Only one case of an apparently permanent cure was observed, which in the fifth generation is still producing offspring with a normal sex-ratio.

These observations suggest that a genetic unit, possibly carried in the cytoplasm, exists in sex-ratio females and is transmitted only through eggs. This unit is responsible for the early death of *XY* zygotes, when present in a threshold concentration. High temperature inhibits or partially inactivates it, thus decreasing the probability of its presence in *XY* zygotes in amounts above the threshold. The complete data will be presented in another publication.

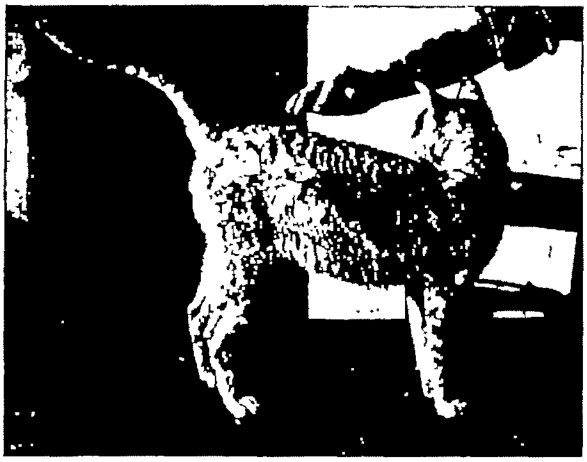
A 'Rex' Mutant in the Cat

In the house-mouse, five genes are known with much the same action on the fur: shortening the guard-hairs, curling the whiskers, and making the baby coat (sometimes the adult too) wavy[1]. Three recessive genes in the rabbit, rex-1, rex-2, and rex-3, affect guard-hairs and whiskers as in the mouse mutants; the fur is not wavy, however, but is short and plush-like. There are also similar mutants in the rat[2].

A similar 'rex' type of mutant has now turned up in the cat (see accompanying photograph). The fur of affected kittens is wavy; later it becomes very woolly to the touch, just like a young rex rabbit. The adult hair is curly but has the velvet texture of



Original male mutant of 'rex' coat-type in the cat

the rex rabbit; the whiskers are curled. The original mutant (a male which also carries the sex-linked gene for yellow hair colour) has been mated to his tortoiseshell mother. Seven kittens have been produced so far, of which three have been rex. So the condition is inherited; but it is not yet possible to tell whether as a recessive or a dominant.

It is hoped to publish further details later.

Inhibition of Superovulation in the Rabbit

The horse pituitary extract *AP*.118.*B* induces superovulation in albino does at 12 weeks of age, provided the animals are fed at a high level from birth. Treatment consists of six subcutaneous injections of this pituitary extract at 12-hr. intervals, followed by an intravenous injection of 25 I.U. prolan 12 hr. later. When this treatment was repeated in the same does at 28-day intervals, in 95 per cent of the experiments the ovarian response was poor and ovulation did not occur. Ovulation did occur at sexual maturity, but only the normal number of ova was shed.

Parkes[1] found that a 10-day as opposed to a 5-day treatment with horse pituitary extract caused a decrease in ovarian stimulation in adult albino does, which suggested that the formation of antibodies might be very rapid.

On the basis of these observations, it was thought possible that the transfer of plasma from a pituitary-treated doe to an untreated one might inhibit ovarian response when the latter was afterwards treated with the same preparation. The results of experiments to test this possibility (see table) suggest that citrated plasma from a doe treated with the horse pituitary extract *AP*.118.*B* has this inhibiting power.

This work, which was carried out during the tenure of an Agricultural Research Council studentship, will be described in detail elsewhere. I wish to thank Dr. A. S. Parkes for making available the preparation *AP*.118.*B*, and Dr. John Hammond and Lord Rothschild for advice and encouragement.

Polyspermy in Mammals

Polyspermy—the entry of more than one sperm into the vitellus at fertilization—is commonly regarded as a pathological process in mammals, with the implication that it leads to early degeneration of the embryo, and this opinion has been expressed by such authorities as Lams[1], Wilson[2], and Hartman[3]. In fact, very little is known concerning polyspermy in mammals, and data on its incidence or consequences are lacking. A study has therefore been made of polyspermy in the rat and rabbit, and a brief account of the results is presented in this communication. A full report is being prepared for publication elsewhere.

In the initial experiments, adult virgin female rats were permitted to mate under normal colony conditions by being placed with males in the afternoon and left with them overnight. Mated rats were recognized by their having a copulation plug when examined the following morning. Sixty-eight mated rats obtained in this way were killed during the day and the eggs recovered for examination in the fresh state with a phase-contrast microscope. These rats provided a total of 627 eggs, of which 614 (97·9 per cent) had been penetrated by sperms. Nine of the penetrated eggs, or 1·5 per cent, were polyspermic; in each of these, one extra sperm had entered the vitellus. The polyspermic eggs were in various stages of fertilization when examined; in two eggs the sperm heads were undergoing metamorphosis and pronuclei had not yet formed, but both midpieces and both acrosomes could be distinguished as they lay in the egg cytoplasm. The remaining polyspermic eggs were in different stages of pronuclear growth, and in each one the extra sperm midpiece and the extra pronucleus were clearly seen. It was noticeable that the two male pronuclei were almost identical in size and appearance.

In the light of previous (unpublished) observations, it was decided to test the effect of delayed mating upon the incidence of polyspermy. Between 8.0 and 9.0 a.m., rats that showed an oestrous smear were selected, and it was known[4] that in such animals ovulation had probably taken place between midnight and 4.0 a.m. the same morning. These animals were placed with males from 9.0 to 10.0 a.m. and were then examined for the copulation plug. Those with plugs were killed at 9.0–11.0 a.m. the following day.

From thirty of these rats a total of 265 eggs was obtained, of which 237 (89·4 per cent) had been penetrated by sperms. Of the penetrated eggs, 22 (9·2 per cent) were polyspermic. These polyspermic eggs either showed the later stages of pronuclear growth or the formation and mitosis of the first segmentation spindle, or else had completed the first cleavage and were in the 2-cell stage. Pronuclear stages were similar to those seen in polyspermic eggs from rats mated at the normal time: two male pronuclei were present in each egg and they were almost identical in appearance. In nine of the polyspermic eggs the chromosomes in the prophase or metaphase of the first segmentation mitosis were visible; in each egg only a single group of chromosomes could be found. Seven of the polyspermic eggs had undergone the first cleavage and were apparently quite normal except for the presence of a second midpiece in the cytoplasm of the blastomeres. As there were no pronuclei in the eggs in the last two groups, diagnosis of the polyspermic state depended upon the finding of two sperm midpieces within the vitellus and the recognition of the early signs of disintegration in these midpieces. This evidence is readily appreciated and aids in the distinction between sperms that have entered the vitellus of the egg and 'supplementary' sperms that have only penetrated the zona pellucida.

In a further experiment, eighteen rats which had been induced to mate after ovulation, at 9.0–10.0 a.m., were not killed until three days later. Five of these rats yielded six polyspermic eggs, four 4-cell and two 8-cell, which appeared normal in all particulars except for the presence of the extra sperm midpiece. Both the sperm midpieces were clearly within the cytoplasm of the blastomeres and showed the degree of disintegration that is seen in the monospermic 4-cell and 8-cell eggs.

Polyspermy is more difficult to diagnose in rabbit eggs, for it has not been found possible to identify the sperm midpiece within the vitellus, although sperms may readily be discerned with the phase-contrast microscope in the perivitelline space. Diagnosis, therefore, could only be made on the finding of three or more pronuclei within eggs which were otherwise normal in appearance. Eight female rabbits were permitted to mate and were killed 16–19 hr. later. From these animals, 57 eggs were obtained of which all showed evidence of sperm penetration but three had no pronuclei. Of the remainder, 53 had two pronuclei each and one was classed as polyspermic: the latter had three structures resembling pronuclei, though they were not very clearly discernible.

In a second group, thirteen female rabbits received an intravenous injection of chorionic gonadotrophin for the induction of ovulation, and were allowed to mate 10 hr. later, that is, at about the time of ovulation. The rabbits were killed 12–13 hr. after mating and a total of 85 eggs was recovered from them for study; 62 eggs showed evidence of sperm penetration, but in only 47 could pronuclei be seen. Eight eggs, 17 per cent of those with pronuclei, were judged to be polyspermic; seven had three separate and well-formed pronuclei and one had six structures resembling pronuclei of various sizes.

We conclude, therefore, that if polyspermic eggs degenerate during subsequent development, the greatly increased incidence of polyspermy which results from delayed mating may well be of importance in animal breeding practice. All the polyspermic rat eggs observed had been penetrated by one extra sperm and the evidence obtained points to both sperms playing their part at syngamy and thus contributing their complement of chromosomes to the zygote. Polyspermy could thus be a source of triploidy in the mammalian embryo, and some instances of the 'spontaneous' triploidy observed by Beatty and Fischberg[5] in mouse embryos may be referable to the same cause.

Absence of a Lansing Effect in *Drosophila subobscura*

Lansing[1] has conducted experiments to show the effect of maternal age on the length of life of the parthenogenetic rotifer *Philodina citrina*. The median length of life of the 'wild' strain of this species was 21–24 days, and maximum length and the adult rate of egg production were reached on the sixth day of life. A strain was bred from this wild strain consisting of rotifers hatched in each generation from eggs laid on the fourth day of parental life. Other strains were established, with parental ages in each generation of eleven and of sixteen days. In the fourth-day strain, the mean expectation of life increased over several generations, and the age of attaining the adult rate of egg production was delayed. In the eleventh- and sixteenth-day strains, there was a rapid decrease in the mean expectation of life, the strains reaching extinction in five and three generations respectively. According to Lansing, longevity progressively declines in any strain which is maintained in each generation from eggs laid on or after the sixth day of life. Results similar to those given by *Philodina* were also obtained by Lansing with *Euchlanis triquetra*.

The rotifers are in very many respects biologically unrepresentative. In an attempt to see whether any comparable effect could be detected in an organism of an entirely different reproductive pattern, we have raised and followed through eight generations a stock of the fruit fly *Drosophila subobscura*, in which each generation was hatched from eggs laid after the thirtieth day of imaginal life.

Flies of the structurally homozygous Küsnacht strain were mated at random within 24 hr. of eclosion and kept in pairs in vials, with frequent transfers, until the thirtieth day, when the survivors were transferred to breeding bottles and their progeny reared. Life tables were constructed for each generation. From analysis of these the following mean expectations of imaginal life were calculated.

	Number of flies in sample	Mean expectation of life from eclosion (days)	Sampling error of mean (days)	S D
F_1	72	23·95	1·15	9·65
F_2	77	24·18	1·15	10·12
F_4	95	22·31	1·18	11·55
F_8	129	24·69	0·877	10·13

From these results it would appear that there is no significant change in the longevity of *Drosophila subobscura* bred for eight generations exclusively from flies older than thirty days from eclosion.

In his publications, Lansing relates the appearance of the maternal age effect to the cessation of parental growth, which represents, in the rotifer, only the cessation of increase in volume, since no further nuclear division within the syncytium takes place after hatching[2]. A maternal age-effect related to growth-cessation might be expected to be absent in an organism such as *Drosophila*, where metamorphosis is complete, although Alpatov and Pearl[3] found that factors affecting the rate of larval growth also affect the longevity of the imago. *P. citrina* lays about twenty-five eggs, corresponding to a fixed number of egg nuclei in the ovarian syncytium, and these nuclei are in existence at the beginning of egg laying[4], whereas in *Drosophila* oogenesis continues in cycles throughout imaginal life[4]. The many unique features of rotifer reproduction have long been the subject of study. It is, however, of special interest to the biology of senescence to know whether Lansing's effect is confined to rotifers. We propose to repeat the study upon a crustacean which grows during a part of its reproductive period.

Grateful acknowledgment is due to Prof. J. B. S. Haldane and to Dr. Helen Spurway for advice and help in the management of *Drosophila subobscura*. I am maintained by a grant of the Nuffield Foundation.

Relaxing Factors in Muscle

ACCORDING to Szent-Györgyi[1], muscle in the relaxed state is characterized by the dissociation of actomyosin into actin and myosin.

One of us (M. C. G.)[2], using the glycerated fibre preparation[1] of rabbit psoas muscle, has confirmed this by showing that ionic media which produce dissociation of actomyosin[3] cause a reduction in elastic modulus of the fibres under isometric conditions, although in all these cases the conditions are unphysiological. Elastic modulus here is a well-defined quantity, well-washed and preserved fibres having Hookean elasticity which corresponds to the value found by Hill[4] for intact muscle in tetanus, and is some five times greater than for the same muscle in the resting state. An alternative proof is given by the temperature dependence of tension (Varga[5]). Fibres under isometric tension in the presence of adenosine triphosphate are relaxed by reducing the temperature, actomyosin formation being an endothermic reaction, and there is also a corresponding reduction in elastic modulus as measured by quick stretch or release.

The question was then: What makes a reversible dissociation under physiological conditions? Attempting to answer this, it was found that a watery extract (1 : 1 by weight) of fresh muscle mince contained a factor which, in presence of adenosine triphosphate (4 m*M*), has a powerful dissociating action, judged by complete relaxation of the fibre, and fall of elastic modulus, although the total ionic strength was only 0·05 *M* (adenosine triphosphate only dissociates at ionic strength greater than 0·25). Further, this action was reversible with *p*H, the range 6·0–7·5 sufficing for complete relaxation and contraction respectively.

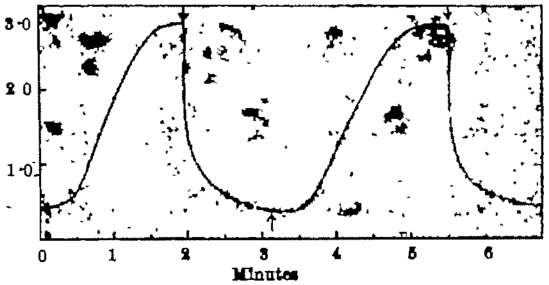
We then began a systematic investigation of this factor from muscle extract using the *p*H dependence of isometric tension of glycerated fibres as a quantitative method of assay, the variation of *p*H being made by a current of carbon dioxide or nitrogen alternately, and the percentage relaxation from maximum tension being taken as measure of activity.

We finally obtained a crystalline substance (as calcium salt from ethanol and recrystallized four times) which was analysed as creatine phosphate and had the following properties: (1) 10 m*M* gives maximal activity; (2) 2 m.equiv. magnesium ions is necessary; (3) 0·8 m.equiv. calcium ions inhibits completely; (4) *p*H range required, 6·2–6·6.

The accompanying record shows a direct record of tension cycle produced in this way with a glycerated fibre bundle. In all tests, 4 m*M* adenosine triphosphate and 1 m*M* magnesium chloride were present, and the ionic strength of potassium was made up to 0·1 μ. Large amounts of magnesium chloride did not antagonize the inhibiting effect of calcium chloride (ratio 100 : 1). Synthetic[6] sodium creatine phosphate gave the same results as the product obtained from muscle. In absence of adenosine triphosphate there was no relaxation or decrease of elastic modulus.

In the absence of creatine phosphate fibres, the *p*H dependence of tension developed by adenosine triphosphate alone (between *p*H 7·5 and 5·8) amounts to 25 per cent, and is established somewhat more slowly[7]. In estimating activity this control should be made.

After standing in 50 per cent water glycerol for several months, the fibres show a loss of activity,



Tension of isometric contraction. ↓, Carbon dioxide, *p*H 5·7; ↑, nitrogen, *p*H 6·6 though their contractility remains unimpaired. By washing with 0·05 *M* sodium bicarbonate – glycerol, the activity was lost entirely in five days at − 20° C. It could be restored by incubation for 30 min. in dialysed muscle extract. This factor *X* appeared repeatedly in the fraction obtained between 50 per cent and 70 per cent saturated ammonium sulphate precipitation, and withstood exhaustive dialysis. We concluded that *X* is probably a protein-enzyme for which creatine phosphate is a necessary substrate.

After long bicarbonate – glycerol washing there was a steady decrease in the speed, though not the maximum tension, of contraction; the speed could be restored by addition of small amounts of cysteine, or of acid-boiled extract which does not contain *X*-factor.

The sharp *p*H dependence of the *X* – creatine phosphate system has special significance for the mechanism of the initiation of the contraction cycle, in view of the *p*H difference 5·8–7·4 estimated by Boyle and Conway[7] which is maintained between the inside and outside of the intact fibre by the membrane. We note here that the work of Marsh[8] and Bendall[9] which reports factors with similar activity makes no reference to *p*H dependence. They appear to agree, however, on the rôle of divalent ions; in this respect there is also agreement with the work of Bozler[10].

Cryptolæmus montrouzieri Mulsant in South India

IN *Nature* of March 1, 1952, Puttarudriah *et al.*, in reporting the occurrence of *Cryptolæmus montrouzieri* near Bangalore, refer to the lack of information on its introduction into India beyond a statement on an index card in the U.S. Department of Agriculture that an unsuccessful attempt was made in 1898.

In the course of some research into the history of the United Planters' Association of Southern India, which attains its diamond jubilee this year, it has been found that this attempt to introduce *Cryptolæmus* into southern India is well-documented, although the documents have been concealed in appendixes to the *Proceedings* of the Association and are therefore not readily available.

At the annual general meeting of the Association in 1896, Mr. H. O. Newport, a planter of the Lower Pulneys (Madura District), raised the question of biological control as a means of dealing with the newly introduced *Coccus viridis* Gr., which was attacking coffee and causing serious alarm, and referred specifically to the work of Koebele in Hawaii. Mr. Newport, an amateur entomologist, had already observed indigenous coccinellids predatory on the *Coccus*, and he pressed the Association to raise funds to organize the introduction of *Cryptolæmus*. In the following year, the Association passed the following resolution: "That this Association do allot Rs. 2,000 from the Reserve Fund to be added to any other sums raised for the purpose of introducing Coccinellidæ into Southern India with the object of combating scale pests. . . . That the Planting Member of Council be instructed to ascertain to what extent the Government of Fort St. George will afford financial assistance. . . . That in the event of a sufficient sum being raised, a qualified person, preferably Mr. Newport, be despatched to Australia and elsewhere to collect and bring back the Coccinellidae". Rs. 6,050 was subscribed, of which Rs. 1,000 came from the Madras Government, and Mr. Newport left India on January 30, 1898, and arrived back towards the end of June with a consignment of some 4,300 adult beetles comprising 2,540 *Orcus australasiæ* Boisd., 1,500 *Cryptolæmus montrouzieri* Mulsant and 246 *Rhizobius ventralis* Erichs. which had been conveyed in ice chests. Subsequent events can best be described in Newport's own words. "Within an hour or so of my arrival there [at his coffee estate in the Lower Pulneys] on the 20th of June, I opened out five of the cases, containing some 2,500 of the lady birds of all three varieties. These I opened out on a cloth on the coffee trees, some in the sunlight and some in the shade. . . . The lady birds, when I turned them out, were mostly clinging to the moss which I had put in the boxes, and they looked healthy enough, only one or two here and there looked seedy. Most of them were full bodied and soft, their legs and antennæ I could move freely with a needle and those that I squeezed were full and moist inside. I could, I regret to say, however, get them to show no signs of life. . . . I had no better success with the second half than I had with the first half consignment".

In the following year, Newport left south India to take up an appointment with the Government of Queensland as instructor in coffee cultivation, so that the matter was not followed up in the area of liberation. There would seem a possibility that eggs or pupæ among the packing could have given rise to viable adults, or some of the apparently dead adults may have survived and escaped observation.

The notation on Dr. Clausen's card files 'Howard 1898' undoubtedly arises from the fact that the Secretary of the United Planters' Association of Southern India forwarded a copy of "Planting Opinion" containing Newport's report on October 5, 1898, and this was acknowledged by Howard on November 7 of the same year.

The combination of depredations by the coccid and a heavy fall in coffee prices led to a considerable decline in coffee growing in the Lower Pulneys, and the local district planters association was wound up in 1899. This, together with Mr. Newport's departure, effectively extinguished interest in this attempted introduction; but it seems that it was more successful than its originator could have dared to hope. The total expenditure incurred on this project was Rs. 4,773, or a little more than £300 at the 1898 stabilized rate of exchange.

FORTHCOMING EVENTS

Monday, July 13—Tuesday, July 14

Physical Society (in the Department of Physics, King's College, Newcastle-upon-Tyne).—Summer Provincial Meeting on Optics and Ultrasonics.

Monday, July 13—Saturday, July 18

University of Birmingham (in the Physics Department, The University, Edgbaston, Birmingham 15).—Conference on Nuclear Physics.

Wednesday, July 15

Royal Meteorological Society (at the Building Research Station, near Watford), at 2.30 p.m.—Summer Meeting.

Royal Sanitary Institute (at 90 Buckingham Palace Road, London, S.W.1), at 2 30 p.m.—Symposium on "Salvage and Utilization of Food Waste for Animal Feeding".

Friday, July 17

Biochemical Society (in the Department of Biochemistry, Bute Medical Buildings, St. Andrews), at 11 a.m.—Scientific Papers.

Saturday, July 18—Thursday, July 23

Physical Society, the Institute of Physics, and the Electrical Research Association (at the Clarendon Laboratory, Oxford).—Conference on "Ionization Phenomena in Discharges".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Senior Psychologist in the Department for Children and Parents, Tavistock Clinic, 2 Beaumont Street, London, W.1—The Group Secretary, Central Middlesex Group H.M.C., Acton Lane, London, N W.10 (July 15).

Agriculturist (with science degree, preferably with honours, and aptitude for research work) in the Field Husbandry Branch, Department of Research and Specialist Services, Southern Rhodesia Government—The Secretary, Rhodesia House, 429 Strand, London, W.C 2 (July 18).

Assistant, Grade B (with good honours degree in pharmacy and/or physiology), in the Department of Pharmacy and Biology—The Registrar, College of Technology, Suffolk Street, Birmingham 1 (July 18).

Assistant Experimental Officer (with general certificate of education (advanced level) or pass degree in biological subjects) in the Poultry Research Centre, Edinburgh—The Secretary, Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1 (July 18).

Demonstrators in Mechanical Engineering (with engineering degree or equivalent, and preferably industrial experience)—The Principal, Royal Aircraft Establishment Technical College, Farnborough, Hants (July 20).

Chemist (with first- or second-class honours degree or equivalent in chemistry, and at least three years postgraduate research experience, with particular reference to study of corrosion of ferrous and non-ferrous metals) in the Ministry of Supply Tropical Testing Establishment, Port Harcourt, Nigeria, to assist in study of effects of tropical conditions on service materials and equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S W.1, quoting F.286/53A (July 25).

Lecturer in Physical Chemistry—The Secretary to the University, The University, Edinburgh (July 25).

Assistant Keeper of Biology (university graduate or holder of the Diploma of the Museums Association)—The Director, Museum and Art Gallery, New Walk, Leicester (July 31).

Research Assistant in Theoretical Physics—The Registrar, King's College, Newcastle upon Tyne (July 31)

Senior Lecturer or Lecturer in Mathematics at the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (July 31).

Senior Research Officer or Research Officer (Textile Scientist) (preferably with several years experience in the textile industry, and academic qualifications of honours degree status in textile science, physics or some branch of engineering) in the Physics and Engineering Unit, Wool Textile Research Laboratory, Sydney, for research into the physical properties of wool fibres or of fibre assemblies, or into the physical principles of textile processes—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C 2, quoting 465/34 (July 31).

Plant Physiologist (with sound fundamental training and research experience) for studies on the physiology and metabolism of fruit under storage conditions in relation to orchard factors—The Secretary, East Malling Research Station, Maidstone, Kent. (August 1).

Technical Officer (with university degree in science or agricultural science, with botany or plant ecology as a major subject) in the Land Research and Regional Survey Section, Commonwealth Scientific and Industrial Research Organization, Canberra, for ecological studies of native vegetation, as a member of a field survey unit which will also include a geologist, pedologist and geomorphologist—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting 570/19 (August 1).

Principal Research Officer (with at least an M.Sc. degree in mechanical engineering or its equivalent, and not less than eight years practical and/or research experience in mechanical engineering) in the Mechanical Engineering Research Unit, South African Council for Scientific and Industrial Research, Pretoria, to undertake research work connected with technical problems in the field of mechanical engineering and particularly fluid mechanics and its applied fields—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2 (Pretoria, August 8).

Lecturer in Agricultural Botany in the University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (August 10).

Lecturer in Physiology—The Registrar, King's College, Strand, London, W.C.2 (August 15).

Cowburn Research Fellowship to undertake research in pathology, bacteriology, morbid anatomy or allied subjects—The Secretary, King's College Hospital Medical School, Denmark Hill, London, S.E.5 (August 29).

Head of the Chemistry–Physiology Group in the Division of Plant Industry, Commonwealth Scientific and Industrial Research Organization, Canberra—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C 2, quoting 130/188 (August 29).

Principal Research Officer or Senior Research Officer (Ref. 130/190) and a Research Officer (Ref 130/191) (with honours or higher degree in a biological science, or equivalent qualification; for the senior position, experience of research in population genetics or biometrical genetics would be an advantage) in the Genetics Section. Research Officer (Ref. 130/192) (with honours or higher degree in science or agriculture, or equivalent qualifications, with training in plant pathology or mycology) to undertake plant disease investigations, and in particular to study fundamental aspects of host pathogen relationships and the mechanism of resistance to disease, and a Research Officer (Ref. 130/193) (with honours or higher degree in science or agriculture, or equivalent qualifications) to engage in fundamental studies of plant virus diseases, particularly the mechanism of virus multiplication in relation to resistance and susceptibility, in the Microbiology Section; Research Officer or Senior Research Officer (Ref. 130/194) (with honours degree, preferably with botany as major subject, and with postgraduate experience in the fields of work indicated) to undertake detailed studies of pasture plants and others of potential use to Australia which have shown distinct promise, in the Plant Introduction Section; with the Division of Plant Industry of the Commonwealth Scientific and Industrial Research Organization, Canberra—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (August 29).

Lecturer in Geography (with qualifications in physical geography, preferably geomorphology and biogeography, and ability to teach cartography and field survey) at the Auckland University College, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (Auckland, August 31).

Reader in Geography in the Durham Division of the University of Durham—The Registrar, University Office, 46 North Bailey, Durham (September 10).

Stanley Elmore Research Fellowship in Metallurgy in the University of Cambridge—The Professor of Metallurgy, Department of Metallurgy, Pembroke Street, Cambridge (September 15).

Assistant in Metallurgy and Physical Chemistry—The Registrar, Loughborough College of Technology, Loughborough, Leics.

Assistant Lecturer in Civil Engineering (with good honours degree and at least two years practical experience)—The Registrar, The University, Nottingham.

Electrical Engineers and Physicists (with first- or second-class honours degree or equivalent in physics or electrical engineering and interest in electronics, servo mechanism theory or analogue computing) in the Ministry of Supply, Farnborough, Hants, for theoretical and experimental research on design and performance of new weapons and associated guidance and control systems; instrumentation of flight trials and analysis of trials data—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.168/53A.

Engineer or Physicist (with honours degree in physics, and extensive practical experience of instrument development) in the Division of Atomic Energy (Production), Capenhurst, Chester, to take charge of centre engaged in the development of electrical, electronic, mechanical, pneumatic, chemical and optical instruments used for controlling chemical and physical processes—The Ministry of Supply, Division of Atomic Energy (P), Risley, Warrington, quoting 471.

Lecturer (with thorough knowledge of electron physics, and preferably industrial experience) in Vacuum Electronics—The Professor of Electrical Engineering, Electrical Engineering Department, Imperial College, London, S.W.7.

Research Biochemist, Senior Grade (with at least five years experience in the basic grade of biochemist), at the National Spinal Injuries Centre, Stoke Mandeville Hospital, Aylesbury—The Secretary, Royal Buckinghamshire and Associated Hospitals Management Committee, 9 Bicester Road, Aylesbury.

Research Scholarships in the Department of Chemistry, Colour Chemistry and Dyeing, and other Departments of the College—The Principal, Technical College, Queen Street South, Huddersfield.

Scientific Officer (with honours degree in zoology) at the Edinburgh Laboratory of the Scottish Marine Biological Association to join a team of biologists studying plankton ecology in relation to the fisheries—The Officer-in-Charge, Oceanographic Laboratory, 78 Craighall Road, Edinburgh 5.

USE OF SCIENTIFIC AND TECHNICAL DEVELOPMENT BY INDUSTRY

LIKE its immediate predecessor, which was concerned with scientific man-power, the sixth annual report of the Advisory Council on Scientific Policy, which covers the period April 1952–March 1953*, inclusive, is again concerned with a single topic. The central question engaging the attention of the Council during the past year was the review of the effectiveness of current arrangements for ensuring that the results of research make their contribution to the development of the British economy at the present time—a problem the Council was asked to undertake last summer by the Lord President of the Council, then Lord Woolton. A report on the exploitation of science by industry was submitted to Lord Woolton's successor, the Marquess of Salisbury, on March 27, 1953, and this report is reproduced in full, without further comment, as the Advisory Council's annual report for the year.

Attempting to analyse the reasons for the comparative failure of British industry as a whole to exploit to the full the results of scientific research, the Advisory Council notes that industry is hampered by shortage of scientists and technologists and by the present low level of investment, and recognizes that neither factor can properly be considered in isolation. Many large firms in Great Britain appear to carry on with the minimum of technical change, and backwardness in this respect is, in general, more widespread in the medium-sized and smaller firms. Of the 140,000 manufacturing establishments in Britain, 82,000 employ not more than ten men, few of whom have had the training which is necessary to take full advantage of scientific and technical progress.

The view is accepted that the number of scientists and engineers employed in British industry must be greatly increased and their average quality improved, as well as their distribution within industry; but it is not suggested that an increased supply of scientists and engineers will by itself solve the problem. Their importance must be increasingly recognized by industry: the primary reason why industry as a whole does not make more use of scientists is because large sections of industry, being conservative and complacent, have neither missed them nor asked for them; and in this connexion the Advisory Council refers to the way in which recent scientific and technical developments, by revolutionizing the relations of different industries to each other, have necessitated a new awareness of science among those who direct industry. "It cannot be too strongly emphasized," it is stated, "that unbalanced boards of management, on which technical representation is small or non-existent, are unlikely to be able—even if they were not limited in other ways—to take full advantage of the results of scientific research with the speed and enterprise which are required under modern conditions."

---

* Advisory Council on Scientific Policy. Pp. iv+11. (London: H.M.S.O., 1953.) 6*d*. net.

Technical backwardness in industry, the Council continues, already apparent before the Second World War, may have been largely due to lack of technical awareness and enterprise ; but it has been aggravated by such factors as the domination of the national economy since the War by shortages of steel and power, the urgent need for redressing an adverse trade balance and the demands of rearmament. Such factors have encouraged the development of established industries and also fostered the dangerous belief in some sections of industry that they could afford to ignore the latest developments in science and technology. The view that to-day in Britain we can scarcely expect to live by our industry unless we change the pattern of our production and seek to develop new products and processes, which, by depending on the application of our scientific and engineering skills, will keep us in the forefront, is supported by the export figures which are cited. Last year only £34 million out of £2,500 million of overseas exports represented goods (for example, nylon, penicillin, radar equipment) which were unknown before the War. Even with the inclusion of such things as newer types of aircraft, the figure is still less than ten per cent of the total of United Kingdom exports.

Here, while the report is kinder to British industry than was Sir Henry Tizard in his Messel Memorial Lecture last year, the trend of the argument is the same ; but when the Advisory Council comes to discuss the level of investment, it seems to falter where Sir Henry was firm. As elsewhere in the report, admirable restraint is used, and the view that the volume of investment in manufacturing industry is too low, particularly in the development of new products and processes, is reasonably and lucidly argued. Without over-stressing the validity of comparisons with the United States, the Advisory Council believes that the investment figures given in the report suggest that our competitive position is worsening rather than improving, and that investment in manufacturing industry in Great Britain also compares unfavourably with some European countries.

Nevertheless, while the Advisory Council believes that an increase in the volume of investment in manufacturing industry would do more than any other single measure to assist the better exploitation of science by industry, it hesitates to express views on investment policy. It recognizes, indeed, that the subject cannot be ignored, and refers to the possibility that new investment may be deterred alike by the present policy of dearer money and by the prevailing high rates of taxation. It is noted also that the shortage of risk capital is seriously affecting the quality of investment, so that too high a proportion goes into relatively safe forms, and the Council accepts the view that control by licensing of industrial building now has a negligible effect and that the inducements to research and development already provided under our taxation system leave little scope for further relief.

Holding the view, however, that the most effective single measure which would conduce to a far greater exploitation of science by industry would be a significant increase in the volume of investment, the Advisory Council on Scientific Policy seems to assume that no major change in the existing level of investment is to be expected. No one would expect of the Council a detailed examination of financial and economic proposals or policy, but something might at least have been said of the way in which taxation policy, for example, can affect development and encourage or discourage the adventurousness on the part of British industry for which Sir Henry Tizard called so strongly. Representations, presented with the moderation and lucidity which characterize the report in general, would have been the more welcome from so impartial a body as the Advisory Council in a matter which is all too easily bedevilled by party politics.

Apart from its caution here, which would seem to be due to over-anxiety not to offend departmental or party prejudices, the Advisory Council's report is thoroughly realistic. It is pointed out that the volume of research and development carried out by industry would probably increase if the writing-off of capital facilities, or of special facilities needed to ensure organized scientific development, could be expedited. The contribution of the research associations to productivity and in the fostering of development projects is regarded very favourably, though there will certainly be some dissent from the view that large and medium-sized firms rather than small firms benefit most from the work of the associations. The Advisory Council considers that the policy of the Department of Scientific and Industrial Research of developing the work of the associations in the productivity field is likely to increase most economically the output of medium-sized and small firms, though here again it admits that more investment capital would be required. As regards development, it is suggested that some of the research associations are mature enough to identify requirements, for example, for new types of machinery, in the further development of which the National Research Development Corporation might help.

There are few factors responsible for the failure of British industry to exploit science sufficiently which are not touched upon in this report, though it does not enter on discussion of such matters as the influence of restrictive practices by both management and labour, nor of the effect of Government control on initiative and adventurousness. In a reference to Government Departments and development, the Advisory Council shows itself thoroughly aware of the danger of looking to the State rather than to industry and the individual for initiative and adventurousness ; and there is no suggestion here that there is a lack of either the skill or the physical resources to enable British industry to enjoy a full share of the benefits to be reaped from recent scientific and technological advances. There is no reason for us to be apprehensive, either, in regard to technique. While there is undoubtedly room for the wider extension in British industry of the most advanced practice, there is every reason, too, for confidence in its ability to apply the results of scientific advance, given the conditions which the Advisory Council stresses—a greatly increased number of scientists and engineers and a large flow of capital willing to seek investment in productive industry.

Confidence in the industrial future of Britain is derived from the fact that at least some British firms are as scientifically minded and as progressive as their counterparts in other countries. There is no fundamental technical reason why more should not emulate their example; and the Advisory Council has indicated, albeit somewhat tentatively, ways in which Government action could encourage this. It may well be necessary for others to repeat in more forthright terms what the Advisory Council has put so leniently; but the report also illustrates the need for the continuing survey and representations of the Advisory Council on Scientific Policy over its whole field, if the objectives in even one aspect such as that covered by the present report are to be achieved.

There are undoubtedly real advantages in the Advisory Council presenting its considered views on particular topics in such special reports; but it is perhaps unfortunate, particularly at the present time, that the annual report should be used as the medium of publication to the exclusion of discussion of all other topics. No reason is apparent from either the present, or last year's, report why reports on scientific man-power and on the exploitation of science by industry should not have been issued independently by the Council, and its annual report left free for the discussion of general aspects of scientific policy as appropriate. There are various topics of wide importance at the present time and on which scientists would be glad to know what advice the Advisory Council has given the Government. Has the Advisory Council, for example, accepted without protest the Government's procrastination over the proposed Science Centre, or has it pointed out the detrimental effect that such postponement is likely to have on the dissemination of scientific information and thus on the utilization of science by industry? What action has the Advisory Council taken to expedite Government action in the upgrading of selected technical colleges for higher technological education, or to secure the effective co-ordination of higher technological education under the University Grants Committee, as was indicated in an earlier report of the Advisory Council? The failure of the Minister of Education to formulate a policy does not warrant the Advisory Council in leaving this matter with the hope that the Government's announcement regarding the Imperial College of Science and Technology "will soon be followed by effective action". And is there nothing further to report on the supply of science teachers, which so disturbed the Advisory Council a year ago? Earlier reports have referred also to the utilization of the services of scientists and technologists in the Colonial territories and in the nationalized industries. Has the Advisory Council on Scientific Policy nothing further to say on these subjects? Is it satisfied that full use is being made of the services of scientists and technologists in these fields and that their advice is heeded?

There are, in fact, misgivings among scientists as to the use made of scientific advisers in the Colonial Service. The Secretary of State for the Colonies has so far done nothing to prevent the development of an atmosphere in which responsible men of science are unlikely to accept appointments and from which the Commonwealth will quickly suffer. So, too, on the nationalized industries, so responsible a periodical as *The Engineer*, in commenting recently on the annual report of the British Transport Commission, expressed fears that the changes initiated by the Government might seriously endanger technical efficiency, and expressed regret that political considerations had been allowed to introduce changes in organization of doubtful value which were bound to disturb profoundly the work of the Commission and its executives.

There is, in fact, an accumulation of evidence which suggests that little more than lip service is being paid by the Government to the claims of science to be heard in the counsels of the State and that objective advice is being disregarded. At such a juncture the silence of the Advisory Council on these matters is the more disquieting. It should be a prime function of the Council not merely to present advice to the Government, but also to satisfy the world of science that such advice is presented objectively and effectively, and that it receives due and reasonable consideration. It is to be hoped that means will be found whereby the Advisory Council on Scientific Policy will be able, not only to issue reports from time to time on matters of major topical importance, but also to provide the scientific world with an annual account of its activities in the many lesser fields in which scientific progress impinges on everyday affairs.

THE AGRICULTURAL RESEARCH SERVICE

The Agricultural Research Council, which is appointed by the Committee of the Privy Council for Agricultural Research and Nature Conservancy, is responsible for the general supervision of State-financed agricultural research in Great Britain. Established in 1931, it has marked its coming of age by issuing a 54-page booklet, which is both a directory to the Service and an account of the functions of the Council*.

The recent growth of State expenditure in Britain on agricultural research is remarkable, and reflects the growing recognition of the vital importance of agriculture in the national economy. In 1930 State expenditure on research was about £250,000, in 1940 it was £800,000, in 1950 £2,600,000, and in 1952 £3,200,000. The first figure represents about 0·1 per cent, and the last figure about 0·3 per cent of the gross value of agricultural output in the corresponding year. The figure 0·3 per cent may be considered too low for such an essential industry as agriculture to spend on scientific research; but it should be remembered that it is not the industry but the taxpayer that provides the money, and that until the War the taxpayer had no reason to regard increased agricultural production at home as a matter of urgency. The agricultural research service should be satisfied that a four-fold increase in its cost since 1940 indicates that the public now recognizes its importance.

---

* The Agricultural Research Service. Pp. 54. (London: H.M.S.O., 1953.) 1s. 6d. net.

The agricultural research service has no formal constitution, and the term is used to comprise the activities of the agricultural research institutes and units, numbering between thirty and forty, which are financed by the State and supervised by the Agricultural Research Council. The service grew haphazardly. It may be said to have started in 1843 with the foundation of the Rothamsted Experimental Station—the oldest agricultural research institute in the world—by Sir John Lawes as a private venture. Other research institutes, dealing especially with various branches of horticulture, were afterwards founded by private benefactions or by funds provided by growers' associations. University departments also began research in different branches of plant and animal production. One significant result of this haphazard growth has been that there is no *agricultural* research station in Great Britain; but a number of independent institutes each concerned with some specialized branch of agriculture such as dairying, grassland, animal or plant breeding, etc.

Public money was not provided for agricultural research until 1910, and was at first administered by the Development Commission, which was responsible for allocating the money to the various institutes and university departments and thus exercised some co-ordination over the development of agricultural research as a whole. It proposed the setting-up of several new institutes some of which came into being after the First World War, which had at least established the right of British agriculture to survive. The Government's proportion of the cost of research increased rapidly, and as the need for closer co-ordination in the administration of the public funds grew the Agricultural Research Council was set up, first, to act as scientific advisers to the Development Commission, and afterwards to take over the responsibilities for agricultural research formerly discharged by the Commission. Agricultural research, like medical research and industrial research before it, was thus formally recognized as a government responsibility.

One of the first acts of the Agricultural Research Council was to survey the work of the research institutes with reference to current national needs, and it was decided that research on animal diseases should be expanded. The Council therefore set up the first of its own research stations at Compton, Berks, to study contagious abortion and other diseases of livestock, and afterwards three other stations. Ten smaller research 'units', concerned with special aspects of agricultural science, are also directly administered by the Council and operate in university departments where their work can be most effectively carried out. Through these units the Council can support fundamental research for which the environment and facilities of a university are often more suitable than those of a State-supported research station. In all, the Council has a staff of nearly a hundred qualified scientific workers in its stations and units.

The Council's aim is "to review, co-ordinate and facilitate all agricultural research in progress, to promote new research where necessary, and to ensure so far as possible that the scientific man-power and other resources available are used to the best purpose". Its prime duty is thus co-ordination, the necessity of which is obvious when the wide field of agricultural research, embracing almost every branch of natural science, and the independent status of most of the research institutes are borne in mind. Besides operating the fourteen stations and units directly under its control, the Council gives advice (which, since the Council holds the purse strings, may occasionally amount almost to commands) on research programmes, staff and budgets to twenty-one institutes in Great Britain that derive most of their funds from the Ministry of Agriculture or the Department of Agriculture for Scotland. No central direction of research, however, is attempted, it being a cardinal principle of the Council that research workers should be free to develop their individual interests within the general requirements of the service. Members of the Council are selected mainly on account of their eminence in science and their ability to appreciate the conditions in which scientific research can best be carried out. There appears to be adequate appreciation of the necessity to promote fundamental research, of which a certain amount is done with public money at research institutes; but in general the Council considers that fundamental research is the province of the university departments over which the Council has no control, although it maintains close contact with them and, indeed, makes numerous grants to them to assist lines of research which may assist the solution of some agricultural problem.

Three standing committees—dealing with animal research, plant and soil research, and agricultural engineering—together with the Soil Survey Research Board assist the Council in formulating a research policy, and these in turn can call upon the advice of twenty-five technical committees or conferences the purpose of which is to keep in touch with problems and progress in specific subjects such as animal climatology, foot-and-mouth disease, dairy machinery, bracken control, drainage, red-spider mite and strawberry diseases. In this way a general policy can be drawn up without losing touch with the requirements of the individual research workers on whose ability and skill the Council recognizes the success of the research service must ultimately depend.

Research policy, particularly in agriculture where results appear slowly, must be long-term; nevertheless it has to be related to the shorter-term agricultural policy of the Government. When the Agricultural Research Council was established in 1931 the trend in government policy was towards the encouragement of livestock farming, and, as already stated, the Council paid special attention to research into animal diseases. Its aim is still to keep in step with post-war agricultural policy with its emphasis on an all-round increase in agricultural production. The Council maintains effective liaison with the Ministry of Agriculture and the Department of Agriculture for Scotland through the two Agricultural Improvement Councils that were set up during the War for that purpose and to advise the government departments on the best means of incorporating research results into practice, and the Agricultural Research Council on the problems requiring investigation. The Agricultural Improvement Councils are closely linked with the advisory services which, in their turn, are in direct contact with the farming community. Thus effective channels exist whereby not only can prompt application of the results of research to farming practice be achieved, but equally the demands of the agricultural industry can be brought to the notice of scientists at the highest level. The administration of such a complex service, from the many first-rate scientific intellects now working for agriculture to the vast multitude of farmers who may make use of the sifted and intermingled results of specialized research, is necessarily complex, but it works remarkably well. Much of the credit for that is due to the spirit of partnership with which the Agricultural Research Council has imbued the whole of the research service.

AUTOMATIC CONTROL OF MECHANISMS AND INDUSTRIAL PROCESSES

Servomechanisms and Regulating System Design

By Harold Chestnut and Robert W. Mayer. (General Electric Series.) Vol. 1. Pp. xiii+505. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1951.) 62*s*. net.

Fundamentals of Automatic Control

By G. H. Farrington. Pp. xii+285. (London: Chapman and Hall, Ltd., 1951.) 30*s*. net.

An Introduction to the Theory of Control in Mechanical Engineering

By R. H. Macmillan. Pp. xiv+195. (Cambridge: At the University Press, 1951.) 30*s*. net.

ONE of the most interesting features of the development, during the past decade, of scientific thought in the field of applied science has been the building up of a philosophy of 'systems having a closed sequence of dependence'. Such systems, in the engineering field, may range in type and application from an automatic pilot for the navigation of an aircraft to the control of a complete chemical manufacturing process. Some of the theoretical concepts which have evolved from the coalescence of several independently developed branches of theory concerning control and communication have proved to be of a very general significance, not only in relation to engineering but even in such apparently unrelated fields as economics and biology.

The three books under review, although directly concerned with the engineering applications of control theory, serve to illustrate both the wide scope of the subject and the variety of ways in which it may be approached. All three start from simple fundamental considerations. H. Chestnut and R. W. Mayer, in their book on "Servomechanisms and Regulating System Design", after developing in a straightforward fashion the basic differential equations of electrical and mechanical systems, deal in considerable detail with the method of solution based on the Laplace transform and apply the method to very simple control problems. The central problem of control system behaviour, that of stability, is given very thorough consideration; in particular, steady-state analysis in terms of the Nyquist criterion. This is followed by a fairly detailed review of control system elements, mechanical, hydraulic and electrical, and their transfer functions, and of types of feedback control systems. Then the application of the complex plane plot in system analysis and in system design is treated.

Following this, attention is directed to the advantages for purposes of synthesis, rather than analysis, offered by design methods based on the work of H. W. Bode on the relationship between attenuation and phase in electrical networks, and the 'attenuation and phase diagram' method is developed and employed on representative problems including multiple-loop and multiple-input systems. The book concludes with a chapter describing the use of charts relating the steady state and transient response to the open-loop attenuation characteristics necessary to obtain the response.

This book constitutes an introduction to a practical method of control system design, and the development of the subject is clear and well suited to its direct purpose. It must, however, be recognized that there is a gap between the development from fundamental principles and the design method based on Bode's theorems which is bridged in only a rather slender fashion. There is an excellent bibliography, and a series of examples for solution is given at the end of the book.

"Fundamentals of Automatic Control", by G. H. Farrington, is essentially a presentation of the principles of automatic control applied to industrial processes. Although the principles underlying the automatic control of a process or of a complete plant may be basically the same as those governing, say, the control of position of the output member of some form of electromechanical system, it is immediately evident, on comparing two text-books dealing with these separate branches, that the approach and much of the nomenclature differ widely. This book formulates in a very satisfactory way the mathematical equations representing typical generalized control systems, and develops performance criteria. The theory is built up on considerations relating to the control of such quantities as temperature, pressure, fluid flow or humidity. Of particular interest is the utilization in the solution of process control problems of electrical analogues for the actual physical phenomena involved and the establishment of the equivalent electrical networks. The electrical analogue is also turned to good account in a chapter dealing with systems having distributed constants, the formulæ of the electrical transmission line being used as a basis for the analysis. There are chapters dealing with the principles of plant analysis and with the analysis of controlling units of pneumatic type, and there is a brief final section on control selection and adjustment. Taken as a whole, the treatment is rather condensed, and there are a good many instances of topics being introduced but developed in too sketchy a fashion to be really useful. Process control concepts and nomenclature are in general less obvious and less readily grasped than those of position control, and the introductory sections of the book create the impression that more effort could usefully have been devoted to elucidation and clear statement. The book does, however, give a comprehensive presentation of the process control problem.

The third book, entitled "An Introduction to the Theory of Control in Mechanical Engineering", does, in fact, draw most of its illustrations from mechanical engineering practice; but the treatment is quite general, and electrical elements and concepts are introduced wherever they are useful or appropriate. A particularly valuable feature of this book is the co-ordination of the analysis of systems in terms of transient response with that in terms of harmonic response. Both analyses are developed in a clear and straightforward fashion, and simple statements of their fundamental mathematical bases are given in two appendixes. The treatment proceeds from a study of typical simple systems to the consideration of general transfer functions and control sequences, and finally to graphical methods for the determination of stability and overall response. The book gives an exceptionally well-balanced introduction to the theory of servo systems, and in scope and presentation it is well adapted to the use of undergraduate students.

The other two text-books, although both starting from elementary considerations, have more specialized aims, and they are better suited to the reader whose branch of specialization is already determined.

J. Greig

COMPARATIVE PHYSIOLOGY OF LOWER ANIMALS

A Physiological Approach to the Lower Animals

By J. A. Ramsay. Pp. ix+148. (Cambridge: At the University Press, 1952.) 15s. net.

In this interesting and stimulating book Dr. J. A. Ramsay discusses a number of the more important aspects of comparative physiology which one would expect to find expounded in a text-book; but, by confining himself to a limited number of well-investigated and well-chosen examples, he avoids cluttering up his discussion with that bulk of information by which a text-book often conceals general principles from the beginner. Dr. Ramsay's book is about the physiological processes of living animals, and these are dealt with comparatively, topic by topic, starting with nutrition and ending with behaviour. It is not a text-book, and some important topics are deliberately excluded as unsuitable to the author's purpose. General principles about the working of whole animals are most effectively presented; the physiology of constituent cells is avoided as far as possible. Among many topics discussed in a most lively way may be mentioned the following: the difficulties of digesting plant material in which the protoplasm is enclosed by cellulose walls, methods of trituration, and the breakdown of cellulose by bacteria in the gut; the hydraulic aspects of circulation in the invertebrates, and the functions of the auricles and pericardium; the interplay of musculature and skeleton, including the 'hydrostatic skeleton' of many lower invertebrates as well as the hard skeleton of arthropods and vertebrates. In the final chapter the behaviour of animals is discussed in a manner likely to arouse the spirit of inquiry in not a few of Dr. Ramsay's readers.

The emphasis of the book is on general principles, and therefore on the results of physiological investigation rather than on the means. This may prove a disadvantage to those who have no experience of physiological methods but who understand and accept results more readily when they know how these results have been obtained. There is, for example, a considerable discussion on nervous co-ordination, including the grading of sensation and of motor response. It is theoretically sufficient for this discussion to state that stimulation of a nerve leads to the passage of small potential charges of short duration which travel very quickly. In spite of the diversion which would be created, it might be easier for a student to understand the mechanisms of nervous co-ordination if he was in possession of an elementary picture of the characteristics of the action potential. The presentation of general principles also inevitably leads to some over-simplification: for example, temperature control is stated to be confined to birds and mammals, although it is practised communally by the domestic bee.

These, however, are minor criticisms and will have no validity if the book is used, as it should be, during the first year of a university degree course in zoology. It will, in fact, make excellent reading for a university student's first long-vacation. It should not be used except with a reasonable knowledge of the general zoology and anatomy of many of the types discussed, and will form an excellent companion to these studies; it is therefore only suitable for the most advanced pupils at school. It will prove stimulating and enlivening to all keen teachers of zoology in schools, and not least to those who were trained in less physiological times. There is one obvious mistake in the legend of Fig. 18; apart from this, the book is excellently produced and the text is illustrated with a number of simple and clear diagrams.

J. A. Kitching

BIRDS OF EAST AFRICA

Birds of Eastern and North Eastern Africa

By C. W. Mackworth-Praed and Capt. C. H. B. Grant. (African Handbook of Birds, Series 1, Vol. 1.) Pp. xxv+836+59 plates. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1952.) 45s. net.

This is the first of two volumes—the second is already in the printers' hands—of a work which will be eagerly welcomed by the many people in the eastern parts of Africa who are interested in the rich and varied bird-life of that continent. It has been written by two authorities of high repute in the subject, and they have surely succeeded in their aim "to give others the book they themselves wanted when they first visited and lived in Africa". The area covered is eastern and north-eastern Africa from (and including) the Sudan to the Zambesi.

The authors have been compiling the information for eighteen years. During that time they have published a stream of papers and notes in the ornithological journals, giving facts that were new or clearing up points of difficulty. This has enabled them to issue their summary in handbook form, avoiding discussion and omitting references. For the field worker this has obvious advantages; and for the specialist the details of evidence and argument are available, in addition, on the library shelves.

For each species and recognized geographical race found or occurring in the area, the essential facts are given under the heads of distinguishing characters, general distribution, range in eastern Africa, habits, nest and eggs, food, call and (where applicable) distribution of other races of the species; the particulars relating to reproduction are omitted where the species or race is not known to breed in the area. English and scientific names, with full references for the latter, are of course also given; and the species are consecutively numbered. In addition, there is a brief general note on each family and a key for the identification of the included species.

There are little marginal maps showing the distribution of each species or race. This is an attractive feature, which one hopes to see followed in other works: another book which is in course of preparation has indeed independently adopted the plan. The illustrations of birds include marginal drawings in black-and-white and numerous figures in coloured plates: although the colour reproduction does not seem to be of the highest standard, both are well suited to their purpose. There are also some plates of photographs from life.

The book is very well printed by lithography, and attractively produced. In every way it should be a pleasure to use, and its availability should be a great stimulus as well as help to the further study for which abundant scope remains. An index of English names is lacking, but it may be intended to provide this for the work as a whole at the end of the second volume.

This first volume deals with the non-passerine birds, from ostriches to pittas. The groups that bulk most largely are the herons and storks, ducks and geese, birds of prey (no less than eighty-three species), game-birds, plovers and their allies, pigeons and barbets. Of the last, there are thirty-three species in eastern Africa, including "the Tinker Birds, Brain-fever Birds and others whose monotonous notes have been commented on with varying virulence". The richness of the avifauna reflects not only the extent of the area but also the variety of its country, from desert to primeval forests, from coast to great lakes, and from swamps to highlands, the last culminating in places with the zone of giant heather and lobelias, leading up to snow-clad peaks.

LANDSBOROUGH THOMSON

CHEMICAL CALCULATIONS

Problems in Physical Chemistry

By Prof. Lars Gunnar Sillén, Paul W. Lange and Carl O. Gabrielson. (Prentice-Hall Chemistry Series.) Pp. xiii+370. (New York: Prentice-Hall, Inc., 1952.) 6.65 dollars.

Chemical Calculations

An Introduction to the Use of Mathematics in Chemistry. By Prof. Sidney W. Benson. Pp. xi+217. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1952.) 24s. net.

A TRAINING in calculations is an essential part of the education of a chemist. The student (or the teacher) cannot really understand a quantitative physical law until he has applied it in numerical problems. Books of more-or-less elementary chemical calculations are fairly plentiful; but—apart from Wolfenden's "Numerical Problems in Advanced Physical Chemistry" (1938)—none had been published during the past quarter of a century that was reasonably modern in outlook and sufficiently advanced for an honours class in physical chemistry. This need is now met by the first of the two books under review.

"Problems in Physical Chemistry", by L. G. Sillén, P. W. Lange and C. O. Gabrielson, is an American version, prepared by the original authors from the second Swedish edition, of a book which appears to have been very successful in Scandinavia. It comprises eleven chapters with the following titles: first law of thermodynamics; second and third laws of thermodynamics; partial quantities, activities; law of mass action, gas equilibria; solution equilibria; chemical electromotive forces; solubility, complex and redox equilibria; acid-base equilibria; transport of electricity by electrolytes; rate of reaction; phase boundaries, atoms and molecules. (The ground covered is therefore correctly described in the title as physical chemistry rather than chemical physics.) Appendixes deal with methods of numerical calculation, and give lists of symbols used and of journals quoted and the answers to the problems. There are adequate author and subject indexes.

Each chapter begins with a section (10–20 pp.) summarizing the principles to be used and illustrating them by worked examples, and then sets out a large number of problems for solution. Altogether there are about 750 of these, nearly all of them taken from original papers to which references are given. They are thus real-life problems rather than arbitrary academic exercises, and anyone (graduate or undergraduate) who works through a selection of them will acquire a good knowledge of physical chemistry and its literature. Though the authors explicitly disclaim them as substitutes for a text-book, the introductory sections are excellent; they contain a large amount of useful information in a very concise form and are up to date. Wise guidance is given as to the accuracy of experimental data and to the various levels of approximation needed in calculations based on them. Occasionally the authors comment on the original work used in the problems, and their comments are always most illuminating.

This is certainly one of the best books of advanced chemical calculations at present available. It would be a pity were the rather high price to restrict its general adoption as a standard text for all honours courses.

The other book, "Chemical Calculations", by S. W. Benson, is much more elementary, despite the solemnity of its sub-title. It is intended to coax a first-year (intermediate) student, who has no mathematics, into some understanding of the numerical way of dealing with chemistry. It has seventeen chapters covering the usual range of topics in elementary general and physical chemistry, each chapter ending with a group of ten or twenty simple exercises. The book starts with such matters as converting x grams to pounds or the use of logarithms, and reaches as far as simple ionic and redox equilibria. No calculus is introduced. What it sets out to do, the book does well enough; it is clearly and interestingly written, and—at its level—sound and up to date. (But it surely sets the cart before the horse in calling the van t'Hoff isochore the "Arrhenius equation for equilibrium constants".) To those students who can afford to pay a relatively high price for an elementary book, it may well prove very useful.

J. C. SPEAKMAN

Radio Interference Suppression

As Applied to Radio and Television Reception. By G. L. Stephens. (Published for *Wireless World*.) Second edition. Pp. 132. (London: Iliffe and Sons, Ltd., 1952.) 10*s*. 6*d*.

In view of the regulations made recently for the suppression of interference in the television frequency band, the publication of this up-to-date guide on suppression methods is opportune. The book is a revised edition of the original publication by G. W. Ingram in 1939. It is intended for all those who have to do with the actual process of suppression, from the designer of electrical equipment to the service engineer who has to cope with specific cases of interference. It is essentially a practical book, and only an elementary knowledge of the theoretical side of the subject has been assumed.

In the first chapter the origin of interference and its modes of propagation are simply explained. After discussing the general principles of suppression, the author shows in a well-illustrated chapter how they may be applied to a wide variety of sources of interference ranging from domestic appliances and motor-car ignition systems to industrial equipment and trolley-buses. A separate chapter has been devoted to marine applications. In discussing the specification requirements of suppressor components, the author rightly emphasizes the need for reliability especially from the safety point of view. Methods of locating interfering sources and of measuring the radiated field strength are briefly described. In the last chapter, on suppression at the receiver, one is rather surprised to find television 'ghosts' and picture flutter included. Also in this chapter occurs an unfortunate disagreement between the text and the caption of Fig. 61 : the text correctly gives the stub length as a quarter of a wave-length. To the engineer and research worker who will regard this volume as an introduction to the subject, the bibliography will serve as a useful guide for further study.

B. G. PRESSEY

Progress in Metal Physics, 3

Editor: Dr. Bruce Chalmers. (Progress Series.) Pp. viii+334. (London: Pergamon Press, Ltd.; New York: Interscience Publishers, Inc., 1952.) 48*s*.

This volume, the third of what was originally intended to be an annual series, compares favourably with its predecessors. Three of the articles, namely, those on properties of metals at low temperatures (D. K. C. MacDonald), recent advances in the electron theory of metals (N. F. Mott) and ferromagnetism (U. M. Martius) are good reviews in established branches of pure physics, whereas the other articles deal more directly with subjects of metallurgical significance. First, there is an excellent review on the crystallography of transformations (J. S. Bowles and C. S. Barrett), and an article on twinning (R. Clark and G. B. Craig) which although interesting does not clarify—a circumstance due rather to the state of the subject than to any defection on the part of the authors. G. B. Greenough contributes a very well-informed chapter on quantitative X-ray diffraction observations on strained metal aggregates, while the article on recrystallization and grain growth (J. E. Burke and D. Turnbull) manages to combine a formal approach to recrystallization kinetics with a critical selection from the massive amount of experimental information which has accumulated in this field. Finally, the editor gives a very readable account of the structure of crystal boundaries.

This series is primarily for research workers, both physicists and physical metallurgists, who have much common ground. However, one might have hoped that the valuable contributions to pure physics, on one hand, would have been balanced, on the other, by some articles more closely related to metal technology. Some effort to bridge this gap was made in the first volume, but not in the present one.

R. W. K. HONEYCOMBE

Mathematical Models

By H. Martyn Cundy and A. P. Rollett. Pp. 240. (Oxford: Clarendon Press; London: Oxford University Press, 1952.) 21*s*. net.

An exhibition of mathematical models staged by the mathematical sixth-form of a school twenty-five years ago was the forerunner of those held to-day by schools, colleges and societies in order to provide that contact with reality so essential in demonstrating ideas and principles in the symbolic world of mathematics. The excellent bibliography shows how scattered is the literature of the subject, and teachers and men of science will be grateful to the two authors for writing a permanent record of these lessons of experience in this fascinating and decorative field.

The carefully written text, with its clear illustrations and photographic plates, gives sufficient detail to enable pupil and teacher to construct many models and diagrams, including dissections, loci and envelopes (by folding, drawing and stitching), tessellations (plane and solid), polyhedra, ruled surfaces, simple machines for solving equations, and linkages. The longest and most attractive section gives nets and constructional hints for the regular, the stellated and the Archimedean polyhedra and their duals, the regular compounds and deltahedra. It certainly is an admirable collection for the classroom.

This delightful book should be in the hands of every mathematics teacher and in every school library.

Personality Development

By J. S. Slotkin. Pp. x+401. (New York: Harper and Bros.; London: Hamish Hamilton, Ltd., 1952.) 36*s*.

The author, who is a social anthropologist, begins by saying that he has tried to work out a systematic theory of personality development, from the hypotheses and evidence of various relevant sciences. The material is, however, systematic only in so far as it has been distributed under four major headings: inheritance, socialization, culturization and individualization. Within each of these fields the approach is mainly descriptive and anecdotal, and is adorned by a wealth of quotations from ancient and modern writers.

It may well be that in the meantime this kind of approach is repaying. Certainly it does not suffer from the aridity of some recent statistical work in the same field. But perhaps we can only be scientific about people if we are content to be dull.

Though no major contribution to the study of personality has here been made, the book is extremely readable and the material is freshly presented. Anyone in search of illustrations for his own lectures or suggestive instances to help forward his own thinking will find that this is an excellent anthology, and perhaps the only one of its kind.

NATIONAL PHYSICAL LABORATORY, TEDDINGTON

OPEN DAY

An open day was held at the National Physical Laboratory, Teddington, on Friday, May 15. In addition to the Laboratory's General Board, which held its annual meeting in the afternoon, the guests included some twelve hundred representatives from universities, government departments and industry. Of the two hundred exhibits, more than ninety had not been shown previously; the following notes describe briefly some of the items which most interested the visitors.

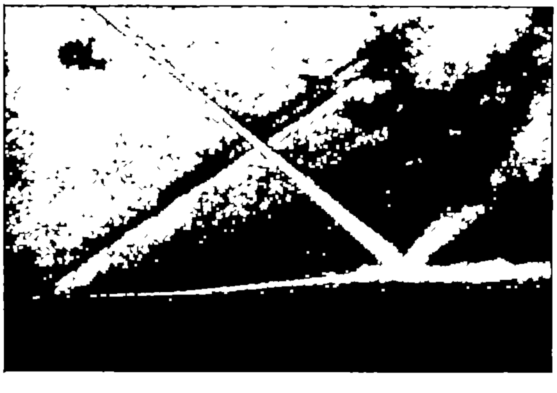
The Collins' helium cryostat, which was demonstrated by the Physics Division, had only recently been installed, but was already producing liquid helium in quantity. This cryostat is manufactured by an American firm and the equipment at Teddington, obtained through the funds of ECA, is the first to be installed in Britain. The great merit of the helium cryostat is that it avoids the use of hydrogen, and the risk of fire and explosion is therefore eliminated. The low-temperature plant at the National Physical Laboratory will be used in the standardization of thermometers and in the study of the crystalline properties of metals such as steel. Work has already been done, using the new apparatus, on the state of internal strain of metal specimens; but the main application, to begin with, will be for the measurement of the entropy of pure chemicals.

The Physics Division also demonstrated methods of measuring radioactive isotopes. Artificial radioactive isotopes are now widely used for medical and industrial purposes, and for certain applications in medical, biological and physical research the highest possible accuracy is desirable. The National Physical Laboratory is collaborating with other laboratories in Britain and with those in the United States and Canada in order to establish national and international standard methods of measurement and standard specimens of radioactive isotopes, particularly for the clinically important isotopes of sodium, phosphorus, cobalt, iodine and gold. As already announced in *Nature*, a service for the supply of standard solutions of radioactive iodine-131 has already been established by the Laboratory, and this service will later be extended to include other important radioactive isotopes. The best accuracy attainable (about ± 2 per cent) in the measurement of the active constituent is less than that traditionally thought of in connexion with other physical measurements; still wider limits are quoted for the more complex isotopes.

Some of the older tunnels in the Aerodynamics Division of the Laboratory have already been closed down and the building in which they were housed has been modified to provide a small lecture hall and to accommodate the Mathematics Division. The up-to-date requirements of aerodynamics research are being met by the provision of new tunnels to augment the existing high- and low-speed tunnels. Two new tunnels, with working sections 36 in. × 14 in. and 25 in. × 20 in. respectively, are nearing completion and will provide the larger-scale facilities required for some of the high-speed work. Both tunnels have a range of Mach number from 0 to 1·8 and are of the induced-flow type. A special strain-gauge balance has been developed for measuring three components of the aerodynamic force (namely, normal force, pitching moment and longitudinal force) acting on a model in a supersonic tunnel. The model is attached to a special form of support, the members of which are stressed by the forces acting on the model, and resistance-strain-gauges cemented to the members convert each of the three component forces into electric signals which operate chart recorders. It is possible to alter the incidence of the model to the airstream while the tunnel is running, and the whole equipment can be remotely controlled.

The phenomena which occur when a shock wave interacts with the boundary layer on the surface of a body are of fundamental importance in most problems of high-speed flow. Experimental studies of the interaction have been in progress at the Laboratory for many years and, as a result of recent experimental and theoretical work, the major features of the problem are now understood. Most of the recent experiments, the results of which were on show, have been made in a specially constructed wind tunnel which enables the Mach number (which determines the effects of the compressibility of the air) and the Reynolds number (which determines the effects of the viscosity of the air) to be varied independently over a large range. An interesting film has been prepared demonstrating the interaction between a shock wave and the boundary layer (see photograph).

The increased use of high-speed wind tunnels has stimulated the demand for small metal aerofoils made to precise limits of form and size. There is a particular demand for 'three-dimensional' aerofoils of the delta-wing type, where the section diminishes progressively from root to tip. It is possible to make such models to any degree of accuracy by cutting a large enough number of tangential planes enveloping the form required. The Metrology Division of the Laboratory has evolved a method of manufacture using an accurately set milling cutter to generate the required tangential planes on the blank, which can be precisely rotated and tilted. The models are made in mild steel or brass and a limited number of planes are cut so as to leave 0·000 5 in. excess metal at the intersection of adjacent planes. The excess



Photograph showing the separation of a laminar boundary layer upstream of a shock wave metal is removed with fine emery, and after final hand-finishing the surface is accurate to within 0·001 in. of the required form. The Metrology Division has also developed a simple microscope method of checking the dimensions of the models and relating measurements made on one side of the model to those made on the other.

The Division has recently acquired a special lathe for producing diffraction gratings by the Merton process. The lathe, which will cut accurately spaced threads ranging in pitch from 100 to 30,000 threads per inch, will be used also to produce the surface of the cylinders on which the master threads are ruled. When scribing 30,000 threads per inch, the tool slide, which carries the diamond and which weighs more than 50 lb., travels quite smoothly at the rate of about 1/16 in. per hr. For every inch of travel of the slide, the diamond cuts a groove more than a mile long.

Apparatus for the measurement of the dielectric constants of pure liquids for use as standards for physico-chemical work was demonstrated by the Electricity Division. Standards are required in the range of dielectric constant from two to approximately thirty; and the Division has so far made determinations for benzene, nitrobenzene, ethylene dichloride and *cyclo*hexane. Benzene from four different sources of supply has been used, and the agreement between the results obtained after two distillations and a drying process is very satisfactory. The value obtained in each case, 2·283 at 20° C., is also in close agreement with the less accurate determinations of the dielectric constant of benzene made at the Laboratory in 1926. Ethylene dichloride, which contains impurities affecting the dielectric constant and making its precise determination extremely difficult, has a value at 20° C. of about 10. Nitrobenzene, which suffers from the same drawback, has a dielectric constant of about 35 at the same temperature. *Cyclo*hexane, unlike benzene, is not hygroscopic, and determinations of its dielectric constant give the same value for the 'as received' condition as is obtained after the double distillation and drying process. Unfortunately, there is no standard grade for *cyclo*hexane of high purity.

The Control Mechanisms Section of the Metrology Division has developed a method of storing and tabulating information, using first a magnetic tape for recording the information at high speed. This information is later tabulated by a slow-speed printing device such as an automatic typewriter. In the system used, digits and signals for typewriter operations are stored on single-channel tape as 20-millisecond pulses of one, two, three or four fixed frequencies. Letters can also be stored if two additional frequencies are used. The recording is decoded using frequency-selective filters setting a relay system corresponding to the typewriter operation to be carried out, for example, typing a digit, spacing or carriage return. The standard electric typewriter used has been fitted with solenoids so that it can be operated automatically. The maximum typing speed is about eight strokes per second.

The Mathematics Division showed a card-operated typewriter which has been adapted for use with the ACE pilot model. The results from the latter are obtained on punched cards, and in order to print them a commercial punched card unit has been modified to operate a commercial electric typewriter at a printing rate of eight characters a second. The ACE pilot model itself, the Laboratory's prototype high-speed electronic digital computer, has been working satisfactorily for about eighteen months and has dealt with problems concerned with mathematical physics, linear algebra, ray tracing, flutter in aircraft, etc.

The crystalline appearance of fracture in mild steel when it breaks in the manner usually referred to as 'brittle fracture' is caused by the fracture occurring across the cleavage plane of the individual crystals. An understanding of the mechanism of this type of failure obviously requires a knowledge of the cleavage strength of iron crystals, and the most straightforward manner of determining this strength is by the use of single crystals, so that no interference from grain boundaries will be experienced if the crystal is broken in tension. At ordinary temperatures, a plain single crystal of iron cannot be broken along the cleavage plane by plain tension, as the crystal yields by slip at a much lower stress than the cleavage strength. At lower temperatures (about − 200° C.), the cleavage strength may be less than the yield stress, and if so the crystal will break with a cleavage fracture without appreciable deformation.

For experiments carried out by the Metallurgy Division, small tensile test pieces consisting of single crystals are made by a strain-and-anneal method, the final dimension over the test length being obtained by electrolytic machining, leaving the surface of the crystal in a highly polished condition. The orientation of each crystal is determined by an X-ray method, and the test-pieces are broken in a micro-testing tensile machine, the test-pieces being cooled to a low temperature in specially designed Dewar flasks. Results obtained so far indicate that over a wide range of orientation single crystals of iron are still completely ductile at − 196° C., but a change to completely brittle behaviour may occur if the orientation is such that a 100 cleavage plane is inclined to the stress axis at angles not less than about 80°.

The highly reactive nature of titanium makes the determination of its melting point extremely difficult. The Metallurgy Division has, however, devised a technique which reduces to a minimum the possibility of contamination while the melting point is determined under black-body conditions. The specimen, a small cylinder about ¼ in. long and ¼ in. diameter, rests in a zirconia crucible provided with a lid with a sighting hole. A recess in the base of the specimen ensures that only a small area of metal is in contact with the crucible. During an observation, the filament of an optical pyrometer is focused on the base of a small axial hole drilled in the specimen. The specimen is slowly heated in a furnace consisting essentially of a tungsten spiral surrounded by radiation shields made of tantalum and molybdenum foil. The spiral, shields and electrodes are enclosed in a water-cooled evacuated cylinder. When melting begins, molten metal fills up the hole in the specimen and disturbs the black-body conditions. The furnace is then shut down before the specimen collapses and reacts with the crucible.

The melting points of nickel and iron as determined in this apparatus are within 3° C., and that of platinum within 10° C., of the accepted melting points of these metals. The melting point observations obtained for titanium are reproducible to within

3° C., and a mean value 1,660° C. is considered to be accurate within ± 10° C., which is the estimated accuracy of the pyrometer.

To commemorate the centenary of the date when Kew Observatory first undertook the accurate calibration of barometers, the Laboratory had arranged a small exhibition of historical records and apparatus in the hall of Bushy House. The exhibits included two standard barometers of 1854 and 1858; when it was formed in 1900, the Laboratory took over with the Kew Observatory much of the work on the standardization of instruments which until then had been the responsibility of the Observatory.

NEW MAGNETIC MATERIALS OF HIGH COERCIVITY

By Prof. L. F. BATES, F.R.S.

DURING the past five to ten years, considerable strides have been made in our understanding of the theory underlying the production of materials of high coercivity. According to the domain concept of ferromagnetism[1], we picture a ferromagnetic metal as made up of a very large number of small regions or domains. Each of these is magnetized, more or less to the complete degree of saturation appropriate to the temperature of the material, with the direction of magnetization parallel to one of the directions of easy magnetization, these being the edges of the crystal cube in the case of iron. We think that the initial permeability of a material is determined by the ease with which boundary movements between adjacent domains can take place, so that any domain in which the direction of magnetization is more nearly aligned with respect to an applied magnetic field may grow in volume, at the expense of neighbours the magnetizations of which are less well aligned, simply by boundary displacement.

But let us suppose we are dealing with particles which are so small that they are, in effect, single domain particles with no domain boundaries inside them. It then follows that it may be difficult to change the direction of magnetization of such a particle, particularly if it possesses marked magnetic anisotropy, that is, if a crystal of the substance is much more easily magnetized along certain directions than along others—or if the particle is of a special shape, so that large demagnetization fields may arise if it is magnetized along certain axes of shape. Consequently, it should be possible to prepare permanent magnets from materials which formerly were regarded as quite unsuitable for such purposes, such as pure iron. At the Physical Society Exhibition this year, the Salford Electrical Co., Ltd., exhibited 'Gecalloy Micropowder Magnets' made from finely powdered iron. The powder is given an insulating coating and mixed in a conventional dough mixer with heat supplied from below. It is then prepared in a variety of shapes by the use of special press tools and powder presses. The new products are important because of their lightness—since they are about half as dense as ordinary permanent magnets—and because of their insulating properties. Incidentally, soft iron pole pieces are sintered as an integral unit with sintered alcomax alloys ('Sincomax') by Messrs. Murex, Ltd., who thus make many sintered permanent magnets of intricate shape.

The behaviour of permanent magnets made of 'Alnico' has been explained by Stoner and Wohlfarth[2] on the assumption that the material consists of finely divided particles, shaped as prolate spheroids, embedded in a weakly magnetic matrix. Now, we know that such iron – nickel – cobalt – aluminium – copper alloys are given exceptionally valuable properties by exposing them to a magnetic field while they are being cooled from a high temperature. The permanent magnetization parallel to the direction of the applied field is, of course, obtained at the expense of the permanent magnetization perpendicular thereto. We also know that if we take a single hexagonal crystal of cobalt it is comparatively easy to magnetize the crystal parallel to its axis, while it is much more difficult to magnetize it in the basal plane. Hence, the possibility arises of producing important magnetic materials which may be easily magnetized in one direction, if we can arrange that the axes of the constituent crystals are aligned in a preferred direction.

This problem has been tackled in two ways. Thus, Swift Levick and Sons, Ltd., have produced the commercially available 'Columax', which is an improved grade of 'Alcomax III', in which the equiaxed crystals of the normal alloy are replaced by long columnar crystals in a preferred direction parallel to the direction of magnetization determined during heat treatment in an applied field. The new magnets must always be in the form of simple solid cylinders or rectangular blocks, and cannot be provided with cored or drilled holes; but, of course, this does not preclude their use in many assemblies and iron circuits. Their maximum remanence is about 13,000 gauss and their coercivity between 700 and 740 oersteds. The quantity $(BH)_{\max}$, which is a criterion of suitability as a permanent magnet material, is of the order $6 \cdot 8 \times 10^6$ gauss-oersteds.

A second way consists in making magnets of compressed manganese bismuthide powder[3] (MnBi). Single crystals of manganese bismuthide are hexagonal and have properties resembling those of hexagonal cobalt, but the material has very high magnetic anisotropy and so possesses a very high coercivity; in fact, values of coercivity measured from an I,H curve as high as 12,000 oersteds have been recorded, which would mean that the coercivity as measured from a B,H curve, as normally specified by a manufacturer of permanent magnets, might be of the order of 7,000 oersteds. It would be surprising, however, if stable permanent magnets of a material as brittle as manganese bismuthide, with a Curie point around 350° C., could be prepared as conveniently as those described earlier.

In addition to the above materials, we also have on the market a material of high coercivity which is virtually a Heusler alloy in which the copper in the well-known aluminium–copper–manganese alloy is replaced by silver. Another important new development[4] in powder metallurgy is the production of the materials known under the trade name of 'Ferroxdure', which consist of blocks of compressed oxides of iron and barium. These have coercivities of the order 1,450 oersteds with a value of $(BH)_{\max}$ of about $0 \cdot 85 \times 10^6$ gauss-oersteds.

Naturally, all such materials are of considerable interest because of the special uses to which they may be put by persons of ingenuity.

ACOUSTIC DESIGN OF AUDITORIA*

By P. H. PARKIN and W. A. ALLEN

Building Research Station, Garston

MODERN building acoustics is based on the work of Prof. W. C. Sabine, of Harvard University. At the end of the past century, Sabine defined and measured reverberation time (the period taken for sound in an enclosure to decay by 60 decibels), and established the simple relationship that this time is directly proportional to the volume of the room and inversely proportional to the quantity of sound absorbent present in the room. After this major advance, comparatively little further progress was made until after the First World War when the rapid development of broadcasting and sound films caused a corresponding development of apparatus suitable for making acoustical measurements. After a short period of optimism, when it was thought that the way was now open to the design of perfect auditoria, this new apparatus served mainly to demonstrate the complexity of the problem; the result is that to-day —after twenty years of accurate measurements—we can only claim that auditoria can be designed to avoid major faults such as echoes, but cannot be designed to obtain with any certainty the more positive requirements such as, for concert halls, fullness of tone.

This slow rate of progress is due to three causes. First, sound is a wave motion: the detailed behaviour of a three-dimensional sound field is complicated by the fact that the wave-lengths of sound in air vary from twenty feet to one inch, while the dimensions of the objects which affect the waves are of the same order and are usually such inconvenient materials as wood, textiles or human bodies; further, nearly all sounds are transient. Secondly, the final judge of the acoustical quality of a room is the human ear, which has several remarkable properties, most of which are not yet fully understood. Thirdly, the full-scale experiments possible are limited by the practical difficulties, not least of which is the expense of even the smallest alteration to the interior of a large room. (An exception to the slow rate of progress has been the rapid development during the past few years of knowledge about speech reinforcement systems. Microphones, amplifiers and loudspeakers were all technically excellent when the work of Haas[1], referred to in more detail below, showed how this equipment should be used for giving the best acoustical results.) For similar reasons, we cannot expect a great deal of help in design from the complete theory of the behaviour of sound waves in rooms, but must rely on the simplified pictures of geometrical and statistical acoustics.

With these general considerations in mind, we can proceed to the design requirements for the two main types of auditoria: those for speech, and those for music. We deal here only with the larger auditoria. For speech this nowadays implies the use of a speech reinforcement system and will be illustrated by reference to the system designed for St. Paul's Cathedral[2]; for music the Royal Festival Hall, London, will serve as an example[3].

Both types of auditoria are the better for a low noise-level; but with a speech reinforcement system this requirement is not so critical as it is for unaided speech or for music. It appears from the experience with the Festival Hall that a very low noise-level (of about twenty phons) is a positive advantage in that it enables an orchestra to play very quietly, thus, for example, increasing the artistic effect of crescendoes. From measurements of the noise-levels on a site and from the known sound-insulation values of most forms of construction, it is possible to design fairly accurately to get a given level of noise inside a building; greater accuracy, however, would be desirable when it is remembered that it is necessary to double the weight per unit area of a wall in order to increase the insulation by 5 db. In practice it is most important that the doors and windows (if any) should be suitably designed so that they do not nullify the insulation of the main structure, and the ventilation plant must also be carefully designed.

Dealing now with auditoria for music, the important musical requirements can be stated fairly definitely, at least in musical terms if not physically. They are fullness of tone, definition, blend, balance and no echoes. Taking them in reverse order, echoes can usually be avoided in the design or, failing this, can be eliminated in the completed building by suitable treatments of the offending areas. Balance, by which is meant the correct loudness ratios between the various sections of an orchestra, is partly a matter for the conductor, and the designer can be satisfied if he gives all the instruments an equal chance. This means in practice that the orchestral platform should be completely raked from front to back. Blend—the possibility of hearing an orchestra as a homogeneous source—is not entirely dependent on the acoustics, but is probably best helped by having surfaces close to the orchestra which reflect some of the sound directly back to the orchestra.

The first two musical requirements—fullness of tone, and definition (and their many synonyms)—present the worst problems to the designer. Fullness is difficult to define, even in musical terms, although it is easily recognized; all we can say is that it is the satisfactory quality added to the sounds produced by musical instruments when in a concert hall as compared with them in the open air. We cannot say for certain what acoustical factors control this quality; the only factor we have under any control is the reverberation, and the most reasonable supposition is that, when designing a concert hall, the longer the reverberation time can be made the more chance there is of obtaining adequate fullness of tone.

Definition has two main characteristics: the first is concerned with hearing the full timbre of each instrument; the second is concerned with hearing every note distinctly so that, for example, it is possible to hear all the separate notes in a very rapid passage. This quality is obtained when the intensity of the direct sound reaching the listener from the source is greater than the intensity of the reverberant sound. The intensity of the direct sound will vary from the front to the back of a hall due to two factors: the first is the usual inverse square law, and in a large hall the difference in intensity between the front and back rows will be of the order of 20 db.; the second is the absorption of the direct sound as it passes over the audience at grazing incidence, although this can be minimized by raking the audience seating. However, it appears that definition can be maintained if the true direct sound is followed shortly after by strong reflexions, and thus a reflector should be suitably placed close to the orchestra to reflect sound towards the rear of the hall. This method has been successful in the Festival Hall, where the reflector suspended over the orchestra (and which weighs 12 tons) has maintained the definition over the whole auditorium.

---

* Based on a course of three lectures given at the Royal Institution on November 25, December 2 and 9. The course dealt with the larger types of auditoria, but not film or broadcasting studios.

Although these main criteria for the design of a concert hall can now be regarded as fairly well established, they are, except for reverberation time, all qualitative in character, and there is an obvious need for much more quantitative work.

Turning now to design problems for speech in auditoria, we are on more solid ground. The major single advance in recent years has been the work of Haas[1], who investigated the effect of a single echo on the audibility of speech. Extensions of his work made possible a quite reliable criterion[4] for the transient response of an auditorium. This criterion indicates how a room shape should be designed to ensure that the reflected and reverberant sound gives the maximum intelligibility and naturalness, although there is still need for far more knowledge on the actual behaviour of rooms.

But it is in its application to speech reinforcement systems that the Haas work has so far proved most useful, in two ways. First, a single echo (that is, a delayed reproduction of the original sound, usually coming from a different direction) when delayed behind the original sound by 5–25 msec. has to be about 10 db. greater in intensity to be heard as loudly as the original sound, and at lesser intensities is not detectable as a separate source; secondly, at greater time-delays, Haas determined how loud such an echo can be before it begins to interfere with the speech. For example, an echo of intensity 3 db. lower than that of the original sound is not heard as an obtrusive echo until it is more than 60 msec. behind the original sound.

The applications to speech reinforcement systems are obvious. In a simple system employing only one loudspeaker, this loudspeaker should be placed so that the sound from it arrives 5–25 msec. after the sound from the human speaker. The loudspeaker sound can then be up to, say, 7 db. greater than the original sound without being heard as a separate source. In large auditoria where a single loudspeaker is not sufficient, the same effect can be maintained by using electrical delays. Thus in St. Paul's Cathedral the loudspeakers installed down the nave are delayed by time intervals corresponding to the path differences between the pulpit and the listener plus 5–25 msec., so that all the sound appears to be coming from the pulpit. The second Haas result can be used to ensure (by suitable directivity of the loudspeakers) that the sound travelling back towards the source is at a sufficiently low intensity to avoid interference.

An interesting further application of this work, although not yet tried in practice, would be in debating chambers and other similar auditoria where the original sound might come from anywhere in the floor area. Thus we can envisage a rectangular chamber split into a number of zones each with its own microphone and loudspeaker. When speech is coming from one zone, the loudspeakers in all other zones are automatically switched to have the proper time delays and amplitudes so that the sound received at any point conforms to the Haas criteria.

One more development in speech reinforcement systems should be mentioned. It has been noted that to maintain intelligibility in the presence of reverberation it is necessary for the intensity of the direct sound to be greater than that of the reverberant sound. Now, with an ordinary loudspeaker radiating more-or-less equally in all directions, the intensity of the direct sound has fallen, due to the inverse square law, below the intensity of the reverberant sound at quite a short distance away. But if we use a directional loudspeaker so that most of the energy is radiated towards the listeners, although, of course, the inverse square law still operates, the intensity of the reverberant sound is so much less that the loudspeaker is effective over a greater distance. This is most conveniently done using a vertical line-source which in the vertical plane is sharply directional, producing a main lobe perpendicular to the line and several subsidiary, negligible lobes. At St. Paul's such a line source, 11 ft. long, placed close to the pulpit is effective over the whole dome area (110 ft. in diameter) in spite of the very long reverberation time.

In conclusion, reverting to concert halls, as our knowledge of the desirable acoustical characteristics increases it may become possible to use electronic aids for music as well as speech. For example, in any large modern concert hall it is difficult to get a long enough reverberation time (by having a large volume and a small amount of absorption) without the risk of serious echoes. It might be possible to introduce artificial reverberation by electronic means which would be indistinguishable from natural reverberation and which, possibly, could be altered to suit the particular type of music being played. But this development is some way in the future.

OBITUARY

Dr. C. E. Walker

Dr. Charles Edward Walker died at his home in Brighton on June 6 at the age of eighty-two. He was educated at St. George's College, Weybridge, and studied medicine at St. George's Hospital, London, where he was assistant medical registrar; he qualified M.R.C.S., L.R.C.P. London, in 1909. After holding a demonstratorship in zoology at the Royal College of Science, South Kensington, he went to Liverpool as assistant director of cancer research and honorary lecturer in cytology to the Liverpool School of Tropical Medicine. He obtained the degree of M.Sc. Liverpool in 1909, and of D.Sc. in 1911; afterwards he went to Glasgow as director of research at the Royal Cancer Hospital. Dr. Walker served in the R.A.M.C. with the rank of major in the First World War in France, Gallipoli and the Middle East. He returned to the University of Liverpool in 1919 as lecturer in histology and associate professor of cytology. He held this appointment until his retirement in 1937.

Dr. Walker's work, largely cytological, was published mainly in the form of contributions to the *Proceedings of the Royal Society*. He was also the author of several books on cytology, heredity, evolution, and the cancer problem. The present revival of interest in the Golgi apparatus naturally recalls his contributions to the subject. He was among the first, twenty-five years ago, to carry out deliberate experiments concerned with the importance of physico-chemical fixation artefacts in the usual tissue sections. His experiments were done with chemical models, employing microscope slides coated with films of mixtures of albumin, lecithin, peptone, together with olive oil and ground egg yolk. The slides were fixed and stained by procedures normally employed for the demonstration of the Golgi apparatus in tissue sections. Structures bearing a striking resemblance to the classical Golgi net were obtained, which led Walker to doubt the existence of the apparatus in the living cell. This work laid the foundations for the more recent investigations such as those of Palade and Claude.

Apart from his scientific publications, Dr. Walker was editor of *Shooting and Fishing* during 1897–1903, and author of "Shooting and Fishing on a Small Income". His tall upright figure, his monocle and his military bearing made him a notable figure in the medical school at Liverpool. His staff knew him as a courteous and kindly man. He skated and fenced. He was a skilful and intrepid yachtsman; in 1904 Mr. Justice Channell awarded him the Challenge Cup, the highest distinction of the Royal Cruising Club, for a single-handed cruise down channel to France and back in his 2-ton sloop *Thebe*.

His wife died last year and he is survived by a son and daughter.

N. M. Hancox

NEWS and VIEWS

Physics in Queen Mary College, London: Prof. H. R. Robinson, F.R.S.

After having held the chair of physics at Queen Mary College, University of London, since 1930, Prof. H. R. Robinson is retiring at the end of the present session. His teaching and research work were greatly influenced by his association with Rutherford, first as a student and lecturer in the University of Manchester and later at Cambridge as the holder of the Moseley Research Studentship of the Royal Society. Prof. Robinson's scientific work has been largely concerned with radioactivity and X-rays. He developed with Rutherford the β-ray magnetic spectrometer, and has spent many years in the study of the application of X-ray methods to the elucidation of atomic structure and to the accurate determination of atomic constants. He has always had a special interest in the history of physics, which he regards as an essential part of the education of all serious physicists. During his long tenure of the chair of physics at Queen Mary College he has become well known to a wide circle through his services to the College and to the University of London. He became a member of the governing body of Queen Mary College in 1945 and vice-principal in 1946. He is a member of the Senate of the University of London and takes an active part in the work of several of its committees. He has also served on the Councils of the Royal Society and the Physical Society. His other interests are indicated by the fact that he has been for many years a member of the governing body of the Old Vic Theatre.

Dr. G. O. Jones

Dr. G. O. Jones, who is to succeed Prof. Robinson, has been reader in experimental physics at Queen Mary College since 1949. He graduated at Oxford in 1938 and worked under Sir John Townsend on high-frequency gas discharges and later at Sheffield under Prof. W. E. S. Turner on physical properties of glasses. He then joined Prof. F. E. Simon as a member of the U.K. Government atomic energy project, working mainly at the Clarendon Laboratory, Oxford, and also for short periods at the University of Birmingham and in the United States as a member of a Government mission. After the War, Dr. Jones was appointed as Nuffield Foundation Research Fellow at the Clarendon Laboratory under Prof. Simon. He prepared the detailed design and directed the construction of the large liquid-hydrogen plant serving the low-temperature department of the Laboratory. Later he worked on the properties of solid helium and of low-temperature glasses. During this period he was retained as a consultant by the Atomic Energy Research Establishment, Harwell. Since his appointment as reader at Queen Mary College, Dr. Jones has made new developments in the techniques of attaining low temperatures and has built up a research team working in the field of solid state and low-temperature physics. In this work high-pressure, magnetic, micro-wave and ultrasonic measurements are being employed in a number of investigations at temperatures down to those attainable with liquid helium. Dr. Jones is a member of the Papers Committee and also of the Low Temperature Group Committee of the Physical Society, and is a representative of the University of London on the governing body of the Sir John Cass College.

Mullard Research Laboratories

Mr. P. E. Trier and Mr. G. Knott have been appointed joint managers of the Mullard Research Laboratories. Mr. Trier, who graduated as a Wrangler in the Mathematical Tripos at Cambridge, was engaged at the Admiralty Signal and Radar Establishment during 1941–50. During the War he developed direction-finding techniques in the metre and centimetre regions. Later he was head of the V.H.F. Communications Group. He joined the Mullard Research Laboratories in 1950 as head of the Communications and Radar Division. In his present appointment, Mr. Trier will direct the Electronics Laboratory and be responsible for work in the fields of communications, radar, special circuit techniques, particle accelerators, special components and materials, valve applications, ultrasonics, and metal physics. Mr. Knott, sometime scholar of Clare College, Cambridge, commenced his career as physicist to the Calico Printers' Association in 1935. During 1937–40 he was engaged in research on X-ray crystallography in the University of Cambridge, and worked on molecular structure factors in relation to complex organic crystals. He is also the author of a number of publications on flash tubes and their use in high-speed photography. In 1940 Mr. Knott joined the Mullard Radio Valve Co., Ltd., first as development engineer on transmitting valves and later on V.H.F. valves. He was placed in charge of the Mullard Vacuum Physics Laboratory when it was formed in 1946. Mr. Knott will continue to direct the work of this laboratory in his new appointment, and will be responsible for V.H.F. valves, gas discharge tubes, and photo-electric devices.

General Electric Co., Ltd.

MR. O. W. HUMPHREYS AND MR. A. L. G. LINDLEY have been appointed to the board of directors of the General Electric Co., Ltd., London. Mr. Humphreys, who is director of the Research Laboratories of the Company at Wembley, Middlesex, joined the staff of the Laboratories in 1925, and in 1927 was appointed to its leading scientific staff in charge of the heat group. He is a vice-president of the Institute of Physics and of the Institution of Electrical Engineers. Mr. Lindley joined Fraser and Chalmers Engineering Works in 1918 as an apprentice, and after spending some years as an assistant engineer in the Mining Department was appointed in 1932 chief engineer of the British General Electric Co., Ltd., of South Africa. Returning to England in 1949, he became general manager of the Fraser and Chalmers Engineering Works.

British North Greenland Expedition

FOR the third year in succession, the Royal Air Force will undertake a series of flights within the Arctic Circle to assist the British North Greenland Expedition. This year's flights, which are required to carry stores for the Expedition, will be made in August by five Sunderland flying-boats of Coastal Command and two Hastings aircraft of Transport Command. On August 1, five Sunderlands of No. 201 Squadron will leave R.A.F. Station, Pembroke Dock, South Wales, for Greenland. Their base will be at Young Sound, on the north-east coast (lat. 74° 29′ N., long. 20° 40′ W.), to which the Expedition ship, the *Polarsirkel*, will deliver the stores. On August 5 the Sunderlands will start to fly seventy tons of stores to the Expedition's main camp at Britannia Lake (lat. 77° 07′ N., long. 23° 40′ W.), some 190 miles from Young Sound. The task should be completed in seven to ten days. In mid-August, two Hastings aircraft will leave R.A.F. Station, Abingdon, Berks, for the United States Air Force base at Thule, in north-western Greenland. Their task is to drop some sixty tons of supplies, chiefly petrol, for the 'weasel' tracked vehicles, to the existing advanced camp at position lat. 78° 02′ N., long. 37° 50′ W., now known as 'Northice', and also to establish a petrol dump in a position 200 miles to the west of Northice. The supply drops are due to start on August 20, and should be completed in about ten days; sugar, milk powder and miscellaneous items will also be dropped.

The Royal Air Force made the first flights for the British North Greenland Expedition in July 1951, when a preliminary survey of the ice-cap was made. In 1952, between August and October, five Sunderlands and two Hastings, with a total crew complement of 87 officers and airmen, carried 250 tons of equipment to help the Expedition establish bases. These air operations, apart from making an essential contribution to the success of the Expedition, proved of considerable training value to the R.A.F., since aircrews gained valuable experience in high-latitude navigation and cold-weather flying. The British North Greenland Expedition, of which the Queen is Patron, is undertaking a geophysical, geological and glaciological survey of hitherto unexplored areas of northern Greenland. One of the objects is to establish the depth of the great ice-cap which covers most of the country. The Expedition has now moved its 'weasels' over a glacier to the main base at Britannia Lake, and has relieved the original party of three which occupied the advanced camp at 'Northice'. The 'weasels' are now operating over the ice-cap, and the general field work of the Expedition is progressing according to plan.

Science in Education

IN a speech before Timsbury County Secondary School on June 23, Prof. John Read, professor of chemistry in the University of St. Andrews, claimed that the teaching of mathematics and science should also train students to be exact, accurate, logically minded and precise in the expression of thought. The teaching of science should go still further in encouraging accurate observation and correct interpretation. The three main pillars of education, in spite of the present-day tendency to multiply subjects and introduce more work of a practical nature, are still the three R's: reading, in order to give good command of English; writing, to confer an ability to express ideas clearly and concisely; arithmetic, as the basis of a sound grounding in elementary mathematics. The ideal education should hold a proper balance between science and the arts. Science in itself contributes much to a cultural education. For example, it is difficult to consider a person as being properly educated or cultured who has no basic knowledge of what goes on in the world of Nature around him and also within himself. There are, of course, dangers in a purely scientific education in which a pupil may be overloaded with factual information or furnished with an account of the world which overlooks the moral aspect of the mind. There are plenty of reference libraries available, and this should be recognized together with Plutarch's dictum: "The child's mind is not a vessel to be filled, but a fire to be kindled". In brief, it must be realized that science has its limits as an educative and cultural instrument; but it must be acknowledged that to-day a certain broad acquaintance with science is essential in a world where science has such a profound influence on society and confers so much physical power on man.

Lighter Literature for the Medical Man

A Medical Bulletin, described as "a journal for the profession" and published by Messrs. May and Baker, Ltd., is a periodical different from most of the literature produced specifically for medical men's eyes and minds. Not all doctors will like all of it, but there is little doubt that many doctors must find in it relaxation and a lighter handling of serious subjects, which is often refreshing and sometimes both refreshing and instructive at the same time. It is possible, as several writers in this journal show, to write about grave matters with a disciplined sense of humour which, if it does not convey the facts of which the doctor sometimes gets too many, illuminates the subject from unusual points of view, so that new and instructive aspects of it become evident. This, however, is a difficult art. It is so easy to do no more than reproduce a manner of writing too reminiscent of the medical students' magazines to which many of the adult readers of this *Bulletin* probably contributed. The *Bulletin* also contains some interesting and attractively written articles which are not specifically medical. Those, for example, on the development of the small house in England, which are so charmingly illustrated, would win the heart of any reader or editor; and in the series on the doctor's helpmates, the doctor's wife, who does so much and gets so little public regard, receives the honour which has always been her due. An interesting note on spontaneous combustion, of which 150 cases have been recorded, points a finger at gin and reminds us that Marryat was not romancing when he let poor Jacob Faithful see his mother end this way. Besprinkled with illustrations and with light and often entertaining verse, this *Bulletin* will, we hope, live on to lighten the strain of the busy practitioner's life.

Coconut Milk Growth Factor

THAT the watery endosperm of the coconut contains the growth-promoting 'coconut-milk factor' at all stages of development has been shown by F. C. Steward and S. M. Caplin (*Ann. Bot.*, N.S., 16, 64; 1952). Some activity is also shown by parts of the immature embryo but not by the solid endosperm. Growth-promoting substances of analogous activity have been detected in the immature milky endosperm of maize, in the gelatinous material in immature walnut fruits, and in the young gametophyte of *Ginkgo biloba*. The tissues from which these substances have been obtained appear to grow at the expense of, or to be nourished by, the nucellar tissue. In *Cocos* (coconut), *Zea* (maize) and *Juglans* (walnut) it is the immature embryo that eventually benefits from the growth factor. The conditions that are conducive to the accumulation of the substance seem to involve, or to be associated with, a delay in the growth of the embryo but a precocious formation of the endosperm.

Optics and Microwaves: Conference in Milan

A CONFERENCE on "Optics and Microwaves" was held in Milan during June 9–11, 1952, under the auspices of Unesco, the International Union of Pure and Applied Physics, the Consiglio Nazionale delle Ricerche, the Commissione Nazionale Italiana per l'Ottica, and the Società Italiana di Fisica. A special supplement of *Nuovo Cimento* containing the proceedings of this conference has now been published (Supp. 3 to Vol. 9, Ser. 9; 1952. 2,500 lire). It includes the twenty-seven original communications presented and discussed at the conference and a summary of the work of the conference, written by Prof. R. Malvano, of Turin; a very full account of the discussion is also given. Two of the main subjects treated are the spectroscopy and polarimetry of radiations from infra-red to microwaves; the phenomena of diffraction and propagation (including all the problems relating to the resolving power and to the antenna radiation pattern). Among the most important contributions reported are the following: a microwave spectroscope for the 1·25-cm. wave region (J. C. van den Bosch and F. Bruin); measurement of the velocity of electromagnetic waves and the refractive index of air at microwave frequencies (L. Essen and K. D. Froome); experimental demonstration of microwaves and their optical analogues (G. F. Hull, jun.); applications de la géométrie différentielle à l'optique des microondes (K. S. Kunz); spectroscopy near the boundary between the microwave and infra-red regions (A. H. Nethercot, J. A. Klein, J. H. N. Loubser and C. H. Townes); methods of light optics for the calculation of the diffraction phenomena within the range of centimetre waves (H. Severin); une optique correctrice pour les projecteurs d'onde U.H.F. (J. C. Simon); super-gain antennæ and optical resolving power (G. Toraldo di Francia); and theory and applications of surface waves (F. J. Zucker).

Seminar on Polymer Science

As a continuation of an earlier seminar (see *Nature*, 171, 65; 1953) four lectures were given in the Chemistry Department in University College, London, on June 29. Prof. H. F. Mark described the preparation and properties of co-polymers containing long stretches of monomer units in one single macromolecule. If one stretch of the monomer unit is water-soluble and another stretch of different monomer units is oil-soluble, solutions of the resulting co-polymer have interesting colloid chemical properties. Samples of such co-polymers were demonstrated. Further work discussed by Mark dealt with the structure of polythenes, with the determination of the molecular weight distribution of polymers by a novel method developed by Debye, and with the influence of stress on swelling; the latter effect being demonstrated by a lecture experiment. Dr. C. W. Bunn discussed melting points of chain polymers, and Dr. L. R. G. Treloar outlined the type of conclusions which can be derived from a study of photo-elastic effects of polymers. He showed that in certain cases the stress optical coefficient is a specific molecular quantity which can be used to estimate the length of a statistical chain element. This lecture included demonstrations of photo-elastic effects in crystalline and amorphous polymers. Dr. K. Bailey dealt with certain properties of filamentous muscle proteins. He showed that the rotational relaxation times of these polyampholytes can be estimated by Weber's method (involving the measurement of the polarization of fluorescent light), and he reported results showing in which way these relaxation times are affected by chemical conditions. Each lecture was followed by a discussion which was facilitated by circulating short abstracts in advance.

United States National Science Foundation: Fellowship Awards and Research Grants

FOR the academic year 1953–54 the United States National Science Foundation has awarded 556 graduate fellowships in the natural sciences out of 3,298 applications from all parts of the continental United States, Hawaii and Puerto Rico; in addition, 1,274 applicants were given an 'honorable mention'. 515 awards were made to graduates studying for doctorates (180 first year, 166 intermediate and 169 final year) and 41 to post-doctorate students. The fellowships are awarded on the basis of academic record and recommendations and, in addition, the pre-doctorate students were required to take examinations; in cases of substantially equal merit, the choice was made so as to result in a wide geographical distribution. The list includes 175 awards to those already holding Foundation fellowships, though for the new awards they had to compete afresh. The distribution by subjects is as follows: chemistry, 129; physics, 115; engineering, 63; mathematics, 56; zoology, 38; biochemistry, 35; geosciences, 26; botany, 19; microbiology, 18; biophysics, 14; medical sciences, 13; genetics, 11; psychology and anthropology, 10; and agriculture, 9. Fellows may study at any non-profit institution of higher education in the United States or, subject to approval, abroad. The stipends are 1,400–1,800 dollars for pre-doctorate students and 3,400 dollars for those holding doctorates. The Foundation has also announced the award of sixty grants, totalling 469,550 dollars, to institutions in the United States for the support of studies and conferences on science and scientific education. This is the third group of awards for the fiscal year

1953 and brings the total for the year to 190 grants worth 1,810,200 dollars. The fields covered are astronomy, chemistry, developmental biology, earth sciences, engineering, genetic biology, mathematics, molecular biology, physics, psychobiology, regulatory biology, research education in the sciences, scientific information, studies in science, and systematic biology. The grants range from six months to three years, with an average length of 1·6 years.

Subject Index of British Patent Specifications

Because of war-time difficulties, the printing of subject indexes to British patent specifications since 1939 (Nos. 500,001 onwards) had fallen badly into arrears. Good progress has recently been made in reducing these arrears, but their complete elimination is unlikely to be achieved in less than two years. Meanwhile, searches continue to be difficult and costly. The Patent Office has now permitted Aslib to make 35-mm. microfilm copies of the Patent Office's own Press Mark Indexes and to make them universally available. The Press Mark Index—which will be in most cases the only subject index available in respect of 1939–53 (April 30)—is a fourteen-year cumulative list of the 271 patent classes showing the numbers of the patents in each and their allocation to sub-classes. Microfilm copies of the Index (nearly 8,000 pages) are now available, price £10 10s., from the Director, Aslib, 4 Palace Gate, London, W.8.

Eleventh Conference of the International Federation of University Women

The eleventh conference of the International Federation of University Women, will be held in London at Bedford College during August 6–13, with the British Federation of University Women acting as the host body. More than five hundred representatives from the thirty-one countries affiliated to the International Federation have arranged to attend. A large part of the conference programme will be devoted to business meetings at which the affairs of the International Federation will be discussed and arranged. The Federation is responsible for the award of international research fellowships, seventy-eight having been awarded since its foundation to scholars of twenty-four countries; for furthering the interests of professional women; for the development of cultural relations between members of the Federation in different countries; and for helping displaced university women, of whom there are still large numbers, especially among the elderly. In addition to the business meetings, it is the custom of these conferences to choose a special subject to be considered at a number of public lectures and group discussions; the theme this year is "Human Values in the Technical World", and the conference will open with an inaugural lecture by Sir Henry Self on "London Town", which will deal with the part London has played as a focal point of technical development within the wider field of scientific and humanistic thought. The enrolment fee for the conference is £3 and application forms can be obtained from the Conference Secretary, I.F.U.W. Headquarters, 1 Sedding Street, Sloane Square, London, S.W.1.

Toronto Meteorological Conference

The American Meteorological Society and the Royal Meteorological Societies are to hold a joint meeting in Toronto during September 9–15; the Canadian Branch of the Royal Meteorological Society will be responsible for the local arrangements. The meeting has been made possible by the generosity of the Munitalp Foundation in America, which has made a substantial grant available to both Societies with the view of promoting co-operation and goodwill between them. The programme includes symposia and discussion on the following subjects: ozone and the high atmosphere; cloud physics and induced precipitation; modern cyclone theory; arctic meteorology; radiation; climatic change; micro-climatology; high-level forecasting; general circulation. This will be the first occasion upon which the two Societies have arranged a joint meeting.

Announcements

Mr. L. G. Melville has been appointed vice-chancellor of the Australian National University, Canberra, in succession to Sir Douglas Copland, who has recently assumed office as High Commissioner for Australia in Ottawa. Mr. Melville is Australian Executive Director of the International Bank for Reconstruction and Development and the International Monetary Fund in Washington; he is a distinguished economist, who was formerly professor of economics in the University of Adelaide.

Dr. Carey Croneis has been appointed provost and Harry Carothers Wiess professor of geology in the Rice Institute, Houston, Texas. Dr. Croneis, who will take up his new office in January, was born in Bucyrus, Ohio, in 1901, and holds degrees of Denison, Kansas and Harvard Universities. During 1928–44 he was a member of the geology faculty of the University of Chicago and since 1944 has been president of Beloit College.

The following appointments in the University of London have been announced: Dr. W. St. C. Symmers, senior lecturer in the University of Birmingham, to the University chair of morbid anatomy tenable at Charing Cross Hospital Medical School; Dr. J. H. F. Brotherston, senior lecturer in public health at the London School of Hygiene and Tropical Medicine, to the University readership in public health tenable at that School.

The following appointments in the University of Nottingham have been announced: Dr. Rodney Hill, Research Fellow in theoretical mechanics in the University of Bristol, to the newly established chair of applied mathematics from October 1; Dr. K. W. H. Stevens, Research Fellow in theoretical physics in the University of Oxford, to be reader in theoretical physics from October 1.

Ramsay Memorial Fellowships for research in chemistry have been awarded for 1953–54 to the following: Mr. G. T. Rogers, a British Fellowship of £500 a year in the University of Cambridge; Mr. B. I. Parsons, a Canadian Fellowship in the University of Oxford; Mr. Santos Amer, a Spanish Fellowship in the University of Bristol; Mr. Gines Guzman, a Spanish Fellowship in the University of Oxford; Mr. R. H. Doremus, a United States Fellowship in the University of Cambridge. British Fellowships held by Dr. G. H. R. Summers (Cambridge) and Dr. R. F. Webb (Cambridge) have been renewed for 1953–54.

Work in progress at the Chemical Research Laboratory, Teddington, will be demonstrated at a series of open days during September 22–25. Applications from industrial firms for invitations to the sessions should be sent to the Director before August 31.

BIRBAL SAHNI INSTITUTE OF PALÆOBOTANY, LUCKNOW

By Dr. OVE ARBO HOEG

Director

THE Birbal Sahni Institute of Palæobotany in Lucknow was founded on the initiative of Prof. Birbal Sahni, whose sudden death, on April 10, 1949, caused grief to his many friends and colleagues all over the world. It happened only one week after the foundation stone for the new Institute building had been laid by Mr. Nehru, the Prime Minister of India. This tragic occurrence threatened the existence of the Institute at its very start, and it was only due to the untiring work of Mrs. Savitri Sahni, with the help and co-operation of Sahni's collaborators, and to the sympathetic interest of the Government, particularly Sir S. S. Bhatnagar, that the Institute survived the difficult period which followed.

When founded in 1946 the Institute had at its disposal a nucleus of funds donated by Prof. and Mrs. Sahni and by the Burmah Oil Company, together with Prof. Sahni's collection of fossil plants and his palæobotanical library, also donated for the purpose. The Government of Uttar Pradesh gave the necessary land for the new building, together with various grants. But the main burden has been borne by the Government of India, which, until the end of the financial year 1952–53, has given non-recurring grants for the building and furniture to the amount of Rs. 652,800 and an annual recurring grant which in recent years has been Rs. 150,000. During 1951–53 Unesco, under its Technical Assistance Programme, has helped the Institute by providing a director, a scholarship, and grants for equipment.

The new building was opened officially by Mr. Nehru on January 2, 1953. It was designed by Messrs. A. P. Kanvinde and Shaukat Rai, architects to the Council of Scientific and Industrial Research. It is in two stories; but on the first floor only the front row of rooms has been built. From an architectural point of view it differs from the traditional Indian style in so far as there are no broad verandas along the front. Instead, it has vertical louvres on the south side, which act as sun-breakers, so that during summer no direct rays can fall on the windows.

The total length of the building is 271 ft. There is a 9-ft. corridor along the centre of the building, with laboratories and other rooms on both sides. The window axes are 12 ft. apart, so that, depending on the position of the partitions, there are laboratories approximately 12, 24 or 36 ft. by 22 ft. In all laboratories there are benches along the outer wall, with all service pipes concealed behind the benches. The Institute has its own small petrol–gas plant with connexions to all the laboratories.

The basement comprises workshops and store-rooms. The workshops are well equipped with cutting and polishing machines, bandsaws, etc. In the main store-room for the fossil collection there are racks with interchangeable drawers; the racks have doors and cylindrical dust-traps with cotton wool. Similar smaller racks, for the same kind of drawers, are placed in the laboratories for keeping the specimens which are being studied there.

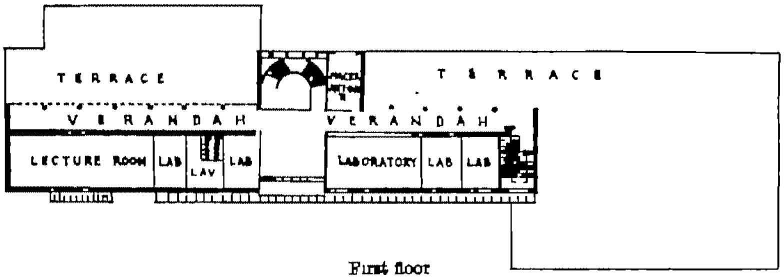
The ground floor, in addition to laboratories and offices, accommodates two large museum halls with a permanent exhibition, and a library, of which a part is provided with a mezzanine floor. There are two darkrooms, one of them air-conditioned.

On the first floor there are laboratories, including a special maceration room with fume-chambers, and a lecture theatre with eighty seats.

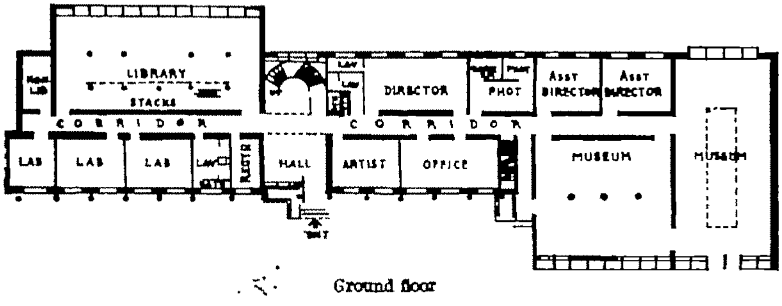
The library of the Institute has as its main core Prof. Sahni's collection of reprints and other palæobotanical literature which he acquired over many years by exchange, gift or purchase, and which after his death has been augmented by the same means. Altogether the library comprises approximately 9,500 reprints, 600 books and 500 volumes of journals. The reprints are stored horizontally on shelves in steel *almirahs*. This method requires more space than the usual vertical arrangement in boxes, but has considerable advantages: the reprints do not bend, they are easily taken out because they are placed in each shelf on a plate of cardboard with a tab hanging down in front, and quarto and octavo sizes can be kept together.

The Institute is publishing a journal, *The Palæobotanist*, of which the first volume was sent out in 1952 as a "Sahni Memorial Volume" (533 pages, 79 plates), and the second volume will appear this year. It is planned that as a rule there will be one volume per year.

The first classical descriptions of the Indian fossil flora, by Oldham, Morris, Feistmantel and Seward, were based on collections which belong partly to the Geological Survey of India in Calcutta, and partly to the British Museum, and also much of Sahni's



First floor



Ground floor

Birbal Sahni Institute, Lucknow

work was based on collections belonging to the Geological Survey of India. The collections in the Institute comprise those brought together by Prof. Sahni and his pupils in various parts of India, and others donated by institutions and colleagues abroad. They include many type specimens and other material described by Sahni and other members of the staff, and they are rapidly increasing, thanks to the field activities which play an important part in the Institute's programme.

The scientific staff of the Institute consists at present of the director (Dr. O. A. Hoeg), two assistant directors (Dr. R. V. Sitholey and Dr. K. R. Surange), one senior scientific officer (post vacant), three junior scientific officers (lecturers), and a number of research scholars and research assistants. Nine scholarships have been granted by the Governments of India and of Uttar Pradesh and by the Assam Oil Company (Burmah Oil Co.). The scholars work on a wide variety of problems, most of them with the intention of submitting theses for the degree of Ph.D. at one of the Indian universities by which the Institute has been recognized.

The Council of Scientific and Industrial Research has sponsored three research schemes in the Institute, each scheme with two research assistants appointed by the Council and a senior member of the scientific staff as supervisor.

The administrative and clerical staff is quite considerable, and in addition there are an artist, a photographer, a mechanic, two section-cutters, and other assistant staff.

The scope of the Institute is to promote palæobotanical research in all its aspects, on an Indian, as well as international, basis. Necessarily, the study of Indian fossil floras will always form the main object of the activity.

Apart from a very few and poorly preserved plant remains from older periods, the oldest flora in India is the Lower Gondwana flora, with *Glossopteris*, etc., connected with the most important coalfields in India. From the younger periods there is an extremely interesting Jurassic flora, mostly in an excellent state of petrification, in the Rajmahal Hills in Bihar, and there are remains of flowering plants, in equally good preservation, in the Deccan Intertrappean of early Eocene age. In addition, there are fossil plants in other places and from different ages. Research on a variety of such material is being carried out in the Institute.

In recent years microfossils, particularly pollen grains and spores, have become more and more important in palæobotany. It happens that they are preserved in great numbers in sediments where macrofossils are few or entirely missing, and they may therefore help to solve age problems in cases where other fossils have failed. It was in recognition of this fact that Prof. Sahni planned a search for microfossils in Indian sedimentary rocks containing no macrofossils and the age of which is uncertain. The plan received the support of the Council of Scientific and Industrial Research in 1947 and is still going on in the Institute.

Peat bogs and lake deposits with an abundance of pollen, like those of north-west Europe, are unknown in India, but even so there are some possibilities of pollen analysis of Pleistocene and older sediments, for example, in clays in Kashmir, some of which have proved to be rich in pollen, and possibly also in the plains. Until now, practically nothing has been known about pollen production of trees and other plants in India; such knowledge forms part of the basis for pollen analysis, and the Institute therefore, in 1952, started an investigation of the pollen in the air at Lucknow. With the support of the C.S.I.R., palynological studies on a broader basis, and a pollen herbarium are now being started.

In 1952 the Institute, again with the support of the C.S.I.R., and in co-operation with the Fuel Research Institute, was able to start another research scheme, the palæobotanical investigation of Indian coals. Studies on microfossils in Indian coals have been going on in the Institute since 1949; but under the new scheme it is possible to give the work a broader basis and a wider scope. The work so far has been concentrated on analysing the contents of spores and pollen in various seams. When a sufficiently detailed knowledge has been gained of the various spore forms and their distribution it will be of interest to ascertain to what extent this knowledge can be used for correlation of coal seams. Such practical utilization has proved to be of considerable value in other countries and has also already in a few cases been tried with success in India.

Prof. Sahni himself scarcely had any higher wish for the Institute than that it should be regarded by every palæobotanist as a home and as a place where scientists, from all parts of the world, could come for research and exchange of ideas. He did not live to see that happen. Now, however, the Institute is established, its doors are open, and palæobotanists are welcome to fulfil the wish of its great founder.

NATURE OF VIRUSES

THE Society for Visiting Scientists is to be congratulated on holding yet another successful informal symposium—this time on the "Nature and Constitution of Viruses". A crowded meeting on May 5, under the chairmanship of Dr. A. S. McFarlane, listened to opening contributions from three leading international authorities in this field.

Dr. P. R. Lépine described the work going on at the Pasteur Institute, Paris, in the study of virus inclusion bodies. He adopted a predominantly morphological approach illustrated by electron micrographs of inclusions seen in rabbit myxoma (which is prevalent at present in France), fowl pox and rabies. He discussed the different types, noting particularly that some appear to consist solely of aggregates of elementary virus particles, whereas others are not uniform in composition. An extreme case of the latter is to be seen in the intracellular polyhedra which characterize some insect virus infections and which contain only a few per cent of virus. Generally, small virus forms or signs of virus particles about to divide were absent from his pictures.

Dr. R. W. G. Wyckoff (United States) also showed some striking electron micrographs, mainly of ultra-thin tissue sections. In the chick chorio-allantoic membrane infected with influenza virus, rods and spheres can be seen at the periphery of infected cells having the dimensions and general appearance of the round and filamentous forms of the virus. The rods show definite indications of originating as finger-like protrusions of the cytoplasm of the host cell, and the spheres appear to originate by fragmentation of the rods. No rods or spheres can be seen inside the infected cells. Rous virus in tissue culture showed no cytoplasmic protrusions of the host cell; but pockets of elementary virus particles are present in the cytoplasm—not unlike some of the inclusions shown by Dr. Lépine. Vaccinia-infected chorio-allantoic membrane, on the other hand, shows some peripheral protrusions in addition to the characteristic brick-shaped particles inside the infected cells. Early in the course of infection a few virus particles are present; but again no small or dividing forms can be seen. In a few cases, chains of particles of standard size can be seen. Pictures of bacteriophage suggest the separate formation of tails and empty heads at an early stage in 'phage production. These appear to arise *de novo* in the host cytoplasm, that is, unassociated with parent particles.

Mr. F. C. Bawden (Harpenden) defined virus as a name for the cause of a transmissible disease with no visible cause. What is studied in the laboratory is a fraction which contains the maximal infectivity in the minimal of chemical substance. In the 1930's the study of the plant viruses was carried out mainly by chemical isolations. Twelve viruses have been isolated in a state of homogeneity, and in pure chemical form all are ribonucleoproteins. They differ among themselves in the ratio of protein to nucleic acid, and electron microscopy has shown differences in morphology. The nucleoprotein appears to be the essential multiplying portion of the virus; but in studying chemically purified fractions it is well to remember that much may have been lost in the purification processes. He reminded the audience, in this connexion, that the removal of a rabbit's ear or tail would be unlikely to affect its reproductive activity.

Mr. Bawden referred to the dark period following infection, when little or no virus is detectable in the cells, and which led him to favour the hypothesis that the virus changes the genetic character of its host. In the course of infection a number of other types of particle are produced besides virus; these have been variously named 'incomplete virus', soluble antigens, etc. No kind of particle has been shown to be the forerunner of any other type, and Mr. Bawden thought it was asking a lot of Nature to turn out millions of particles identical with one another.

In the lively discussion which followed, a great deal of interest was shown in the recent demonstration by Hershey and Chase that, following infection by bacteriophage, the protein shell of the infecting 'phage remains outside the infected bacterial cell, while the nucleic acid enters and is able to initiate virus production even if the protein shells are removed by shearing forces. Dr. R. Markham, in particular, said he was mystified as to how 'phage nucleic acid got into and out of its protein shell and whether the results would apply to other viruses. In a meeting where many interesting points were discussed, this topic seemed to appeal most to the general imagination.

Prof. S. P. Bedson pointed to an inconsistency in the argument about how viruses multiply. It is generally conceded that the rickettsiae and the organisms (? viruses) of the psittacosis group multiply by binary fission; but a different form of multiplication is postulated for the smaller viruses. The main argument in favour of this hypothesis is that following infection of cells by one of the smaller viruses, there is a latent period during which little or no virus can be detected in the cells, followed by a sudden increase in the amount of detectable virus. However, recent experimental work indicates that organisms of the psittacosis group, large viruses such as those of myxoma and vaccinia, and indeed all viruses which have been studied, show a similar type of growth curve. Prof. Bedson argued that if psittacosis organisms multiplied by binary fission, there was no real reason why smaller viruses should not do so also, and the speakers were not prepared to dispute his argument.

Prof. Wilson Smith was sceptical of generalizations in the field of viruses and put forward some experimental evidence with the proviso that, so far as he knew, it applied to influenza virus and nothing else. In general, his evidence lent support to Dr. Wyckoff's view that the virus incorporated some part of the host cytoplasm in it. Heat-treated influenza *A* virus crosses serologically with the *B* virus, and the implication is that both forms have something in common derived from the host, or are contaminated by host protein. On the whole he favoured the former. Mr. Bawden countered with the statement that "one man's impurity is very often another man's biologically important product".

Dr. B. Stocker described the work of Zinder and Lederberg on 'phage transduction as supporting Wilson Smith's hypothesis. He pointed out that the factor which is transduced does not appear to be superficially situated on the transducing 'phage. He also described the behaviour of lysogenic 'phage as evidence that 'phage could be transmitted through different generations of bacteria in the complete absence of the usual structural characteristics.

Dr. A. Isaacs objected to the term fragments of cytoplasm when applied to viruses, and Bawden supported this and pointed to a competition between the cell and the virus for essential constituents.

Dr. McFarlane, in summing up, noted that a major part of the evening had been devoted to considerations of the influence of the host cell on the nature and constitution of the virus. This spontaneous trend, he said, suggests that the matter is of prime importance. Some speakers were prepared to go so far as to say that virus particles are shaped out of pieces of host cytoplasm—possibly out of whole genetic units—while others would only say that molecules with the specific antigenic configuration of the host are incorporated into viruses. A less vocal section of the audience appeared to resent these views and could see few grounds for believing that infecting virus particles did more than borrow some biochemical mechanisms from the host and get on with the job of self-duplication. Dr. McFarlane also remarked on the fact that the crystallographers present were prepared to confer 'crystal' status on the insect polyhedral bodies although these contained only a few per cent of virus. It seemed, therefore, that after crystals are isolated, the search must still go on for the ultimate virus particles.

THE MUSEUMS ASSOCIATION

ANNUAL CONFERENCE AT YORK

THE fifty-ninth annual conference of the Museums Association was held at York during June 22–26 under the presidency of Dr. F. J. North, of the National Museum of Wales. It was on May 3, 1888, that museum curators from all parts of Britain were called by the Yorkshire Philosophical Society to discuss matters of common interest; and a further meeting, also at York, on June 20, 1899, witnessed the formation of the Museums Association.

The Conference was attended by about 330 delegates of whom eleven were from overseas. Except for the presidential address and the papers describing the policy and collections in the four museums in York, the theme centred about "Museums and the Public". The main subject for discussion was the methods of display or presentation for the various kinds of museum and art gallery material. The Conference early admitted that there have been radical changes in recent years, and lively discussion ensued as to whether the so-called 'shop-window technique' had not been over-stressed. Quite wide differences of opinion were also expressed regarding what should be shown in the exhibition cases. It was evident that scientific advances and new materials offer new solutions to the practical problems of exhibition, but that these are not without their dangers if attempted by those without adequate training.

Dr. North, in his presidential address, endeavoured to answer the questions: "Why Museums and Wherefore the Museums Association?". He felt that the irreplaceable contribution of museums is in their power to enable us to recapture the capacity to wonder. He also maintained that our understanding and enjoyment of common things can be greatly enhanced by what museums have to tell us about them. Museums can inspire a lively curiosity about the works of Nature and man, and provide a potential antidote to boredom, one of the greatest evils of modern life. Although by its articles of association the Association is precluded from trade union activities, it can advance the interest of its members and help them to render even better service to the community. The *Journal* and the annual conference provide for the interchange of views and the pooling of experience, while the diploma and training schemes seek to establish a recognized professional status.

Among the specialized papers, Dr. Mary Woodall (Birmingham) dealt with the display of paintings, and Mr. Ian Finlay (Edinburgh) with the display of other art objects. The former paper produced a lively discussion concerning the advisability or otherwise of glazing paintings. Although this is a difficult problem in which many factors must be considered, the balance of opinion veered to the elimination of glass protection. Dr. Woodall also advocated the use of small intimate rooms as well as the lofty and pompous galleries, and preferred textiles for background rather than distempered or painted walls.

Mr. H. Stansfield (Liverpool) described the difficulties of an effective display for botanical material and emphasized the importance of showing living specimens. He also stressed that there is more value in discovering new facts about common plants than in merely pointing out a rare one. He stated that illuminated dioramas can be used to link plants of the past with those of the present day, and advocated the presentation of the economic aspects of botany.

Mr. A. J. Butler (Geological Museum, London) said that it is possible to present geology to the public in a manner which gives pleasure to the emotions and the intellect; it is not a fusty academic discipline. Dioramas showing present scenery and reconstructions of the past, coloured relief models and photographic exposition have already proved their worth. Mr. Butler visualized an extended use of coloured photographic prints and colour films of scenery, and of the international exchange of special photographic exhibits dealing with areas famous for their geology.

Mr. A. Hazelwood (Bolton) suggested an introductory exhibit in zoology illustrating the terms used in classification. He advocated modified habitat groups in which the display is produced with the minimum of scenic distraction and the use of plastic-embedded specimens displayed together with enlarged models.

Dr. Iorworth C. Peate (Welsh Folk Museums, St. Fagans) maintained that a folk museum should represent the natural setting and environment of the life portrayed through the exhibits. It should have a museum building for the systematic display of material and act as a centre for archives and research. It should also contain a lecture theatre for activities illustrating national or regional life. Around the folk museum should be displayed old buildings which have been carefully removed from their original sites and furnished as complete exhibits portraying the normal life of the particular period.

At the annual general meeting, the Association established the 'technical certificate' which will be awarded only to those who attain the required degree of proficiency and will provide official recognition for those who work in museum laboratories and workshops. It will be complementary to the diploma of the Association, which was established twenty years ago as the professional qualification for the administrative and curatorial staff.

At the same meeting the Museums Association Benevolent Fund was launched, the purpose of which is to help members and their dependants in financial difficulties in a profession that with few exceptions is inadequately paid.

Sir Leigh Ashton (Victoria and Albert Museum, London) was elected president for 1953–54, and the next annual conference will be held in Edinburgh during July 19–23, 1954.

INTERNATIONAL RADIO CONSULTATIVE COMMITTEE

FORTHCOMING PLENARY ASSEMBLY IN LONDON

THE seventh plenary assembly of the International Radio Consultative Committee (C.C.I.R.) will be held in London during September 3–October 7, inclusive. This assembly will discuss various technical problems encountered in the practice and development of radio communication, with the view of making recommendations to be submitted to the International Telecommunications Union (I.T.U.). The previous plenary assembly was held in Geneva in 1951; but three of the study groups of the Committee met in Stockholm in 1952 in order to give technical advice and assistance in the assignment of very high frequencies for broadcasting and television services in Europe (see *Nature*, 170, 185; 1952).

The work of the Committee is organized under fourteen study groups, the chairmen and fields of activity of which are as follows: (I) Dr. Ernst Metzler (Switzerland), transmitters; (II) M. Pierre David (France), receivers; (III) Dr. H. C. A. van Duuren (Netherlands), complete radio systems used by the different services; (IV) Prof. L. Sacco (Italy), ground-wave propagation; (V) Dr. R. L. Smith-Rose

(United Kingdom), tropospheric wave propagation; (VI) Dr. J. H. Dellinger (United States), ionospheric propagation; (VII) M. B. Decaux (France), radio time signals and standard frequencies; (VIII) Mr. A. H. Cannon (Australia), international monitoring; (IX) Mr. H. Stanesby (United Kingdom), general technical questions; (X) Mr. N. McNaughten (United States), broadcasting, including questions relating to single sideband; (XI) Mr. E. Esping (Sweden), television, including questions relating to single sideband; (XII) Mr. B. V. Baliga (India), tropical broadcasting; (XIII) Mr. J. D. Many of the subjects under consideration by these study groups are of considerable scientific interest, particularly in the fields of standards and measurements, wave propagation, atmospheric noise, television, and the application of information theory to the improvement in the efficient and economical use of the radio-frequency spectrum. Adequate liaison arrangements have been established between the International Radio Consultative Committee and the International Scientific Radio Union (U.R.S.I.) for the discussion and exploration of subjects of mutual interest. The United Kingdom delegation to the Committee is formed under the auspices of the General Post Office, which is the administration responsible for telecommunications in Britain.

RADIO-ASTRONOMY IN THE TROPICS

By Prof. H. E. HUNTLEY

University College, Achimota

In January 1952, the Physics Department of the University College of the Gold Coast brought into operation a radio-astronomy observatory at Achimota, about seven miles from Accra. Its situation gives the station certain advantages. Unlike stations in higher latitudes, its proximity to the equator makes it possible to survey both the northern and southern celestial hemispheres and to observe the sun at zenith angles which are relatively small throughout the year.

The station's equipment includes a twin aerial array forming an interferometer, each array consisting of eight horizontal full-wave dipoles with ground screen, the spacing between the arrays being 30 λ (λ = 6·7 m.). Preamplifiers are provided at each aerial array to neutralize attenuation losses in the cables and increase the signal/noise ratio. The line joining the arrays being in the east–west direction, the collimation plane contains the meridian. The interference pattern is such that the angular separation of the maxima or minima of central lobes is about 2° in Right Ascension.

The receiver and amplifiers incorporate the phase-changing switch described by Ryle[1]. This delicately adjusted unit was constructed by skilled African mechanics in the science workshops of the University College under the supervision of Fr. J. R. Koster, a lecturer in the Physics Department. The output of the receiver is recorded by an Evershed and Vignoles duplex recorder which employs a siphon pen writing on a clock-driven paper strip, the speed of which can be varied within wide limits.

The construction and maintenance of a radio-astronomy observatory in the tropics occasion certain difficulties which are not encountered in temperate climes. All wood associated with the aerials must be impregnated with creosote against the ubiquitous white ant. Tropical undergrowth which would speedily obliterate the ground screens requires frequent attention. To meet the danger of flooding as a result of tropical rain storms, the hut which houses the receiving equipment is built on piles. Thunderstorms are of such frequency and violence at certain seasons that the register shows little more than a continuous record of lightning flashes. The tropicalization of electronic apparatus is obligatory. Even so, there has been a disappointing series of failures of components, particularly transformers, followed by an unavoidable delay in repairs since replacements must be obtained from overseas.

In certain respects, however, this tropical station has advantages. Such excellent wood as African mahogany is immediately available and cheap. Unskilled labour is plentiful and inexpensive. The African 'lord of the manor' demands only a token rent for the land occupied by the station. There is, moreover, a latitude of choice of pitch which makes the avoidance of man-made electrical interference relatively simple.

The current programme of work in the observatory includes the hour-by-hour recording of ionospheric (*F*-layer) disturbances of radiation received from radio stars. It has already become clear that at certain seasons the incidence of these disturbances is more frequent in tropical than in temperate latitudes. It was a cause of some surprise that they are often of such violence as to obliterate almost entirely the radiation of so conspicuous a radio star as that in Virgo. The sun's activity at noon is of course included in the daily record, so that sunspots and such solar flares as are active at midday are under observation. Less frequent events, such as the occultation by the sun of the radio star in Taurus (June 1953), are observed and should yield useful information. Since the situation of the observatory affords a favourable view of radio stars of low declination, it is hoped to initiate a programme for determining the co-ordinates of their positions.

The staff of the observatory owes much to the interest in it shown by Mr. M. Ryle, of the Cavendish Laboratory, Cambridge, who, recognizing the advantages of a site near the equator, has given valuable advice and encouragement.

INITIAL SPREAD OF MYXOMATOSIS IN AUSTRALIA

By JOHN LE GAY BRERETON*

In spite of the fact that the time and position of the introduction of myxomatosis to wild rabbit populations in Australia are known, the course of the spread of this disease which gave rise to the first epizootics of 1950–51 was unknown. This happened because epizootic centres sprang up suddenly in unsuspected and far-distant places. This led to the supposition that the disease was spread by wind-blown mosquitoes[1-4]. This article advances another

H refers to high incidence, denoting a perceptible change in the population; *L* refers to low incidence, denoting imperceptible change.

hypothesis, with supporting evidence. It is considered to be more acceptable and simpler.

During a survey of the distribution and incidence of the disease in some of the northern rivers of the Murray–Darling system, it was possible to get reports on the time at which the disease was first seen. In this way it was possible to trace the continuous movement of the disease along five rivers and to calculate the rate of movement. From this information it has been possible to reconstruct a likely course of events leading to the distribution at the time of the first epizootics.

Two hundred and twenty station-owners, managers, station-hands and other interested people were interviewed and nineteen were found to have precise information about the date on which they saw the first sick rabbit. Great care was taken to ensure that the correct date was obtained. Some people had diary entries, others could relate the event to other events of well-known date like Christmas Day, sheep sales, etc. It was much easier to determine that the disease was continuous along the rivers, for while many were not sure of the date of arrival, all were sure of whether they had seen sick rabbits or not, and whether the incidence had been high or low. It should be noted that all country people were intensely interested in the disease after December 1950 when it was known to be spreading; and where it was not yet present, people were looking for it. Thus it may be assumed that the first finding of sick rabbits roughly corresponds with the first occurrence of the disease.

The results are set out in Table 1. It will be seen that the movement was at about three miles a day. It is of interest to note that there appears to be no increase in rate when the disease is in high incidence.

From this evidence it is reasonable to assume that the disease always "creeps" and that "passive carriage on high level winds"[3] and "jumps"[1,4] do not occur. This hypothesis may be tested by seeing at what rate the disease would have to move along the Murray and Darling from the first introduction site (see map) in order to have the distribution which was displayed by the epizootics of the summer of 1950–51. In Table 2 is set out the straight-line river distance from the site of the first introduction near Echuca in late May 1950 to the known positions on the northern rivers, and it is clear that the rate is approximately the same as that found on the five rivers studied. This test, therefore, supports the hypothesis. Further, the disease was found to exist at Claraville north of Alice Springs in August 1951[2]. The distance along the waterways from the Bulloo Marshes is about seven hundred miles and the time elapsing is about 187 days, which is again about three miles a day (Table 2 and map). The disease is known to exist at a number of intermediate points[6]. It is noteworthy that this movement occurred during the winter months.

An interesting corollary of this hypothesis is that the disease must have been spreading throughout the winter months of 1950. This is surprising because

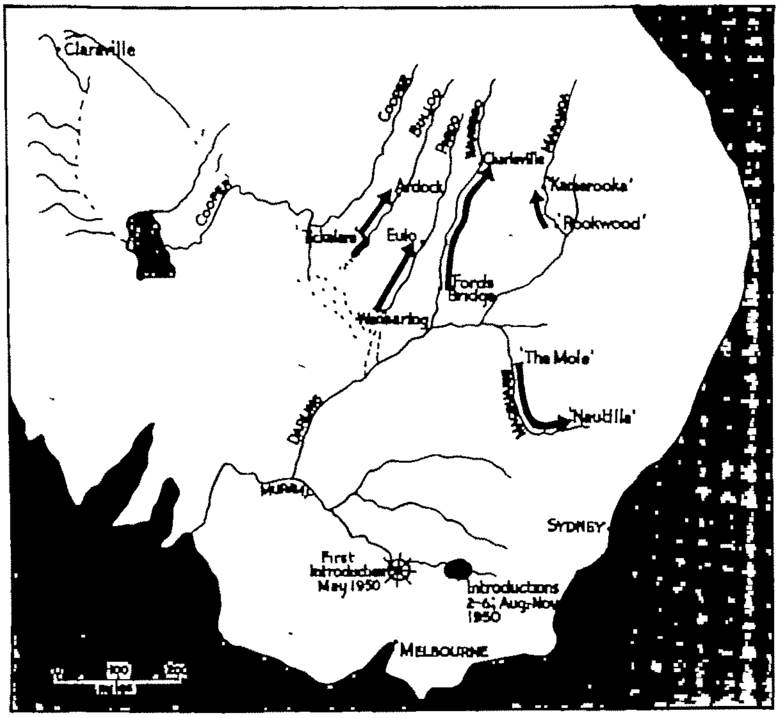

Table 2. Winter Movement of Myxomatosis

From	To	Time (days)	Miles	Rate

insect vectors are thought to be few in winter. Nevertheless, this performance was repeated in the winter of 1951, as has just been shown. Moreover, it persisted throughout its known range, and spread to new localities within this range during the winters of 1951 and 1952[3]. There is no doubt that the disease can spread in winter.

The capacity of the disease to move at low incidence is well shown in Table 2, for much of the movement in the late summer and autumn of 1951 occurred at low incidence. It is worth while to mention here that this movement, independent of season or disease incidence, suggests that the rabbit and not some insect vector is responsible for the movement, while insect vectors have perhaps a greater role in determining incidence. The epizootics always appeared to coincide with abundant insect life, and this in turn coincided with severe flooding and summer temperatures, while the movement of the disease appears to be independent of temperature and humidity.

This movement at low incidence may partially account for the complete absence of reports of sick rabbits during the assumed spread in the winter of 1950. It must be remembered also that the country is very sparsely settled, the graziers in these parts are not concerned about rabbits, such rabbit industry as may exist is not going to advertise diseased rabbits for human consumption should any be found, and, most important of all, no one but a few scientists and officials knew of the presence of the disease in the country. People were not looking for sick rabbits. Further than this, even specialists may miss the disease when it is in low incidence. One experimental site was left by those working on it because they believed the disease had died out; but some months later it flared up here, proving that it had been continuously present. These circumstances may well account for the spread along the Murray and the Darling during the winter of 1950 not being observed.

It has been pointed out how closely this disease is confined to waterways[2]. It is thus of interest to examine how it could shift from the Darling system into the Cooper system. In the first place, we do not know accurately how far the disease does creep from waterways. It was found in scattered places up to twenty miles away from the Macquarie near Trangie. None of these was more than five miles from another. At this time, the Macquarie River was running; but though there is much ramification of waterways in this district and though these waterways had been filled in the floods of November–December 1950, they were dry from February on to June when this particular study was made. The situation in north-west New South Wales, north-east South Australia, and south-west Queensland is similar. There is a great network of waterways which ramify to such a degree that for practical purposes no watershed exists. They are normally dry; but the flooding of December 1950 was exceptionally great. For these reasons then it is not surprising that the disease was able to "creep" into this river system. However, it is noteworthy that it did not appear in the coastal river systems, which are separated by greater distances.

Ratcliffe *et al.*[3] have suggested that because gaps of up to fifty miles exist in the disease on the South Australian coast this is evidence of "jumps". However, it is clear that a patchy distribution is no proof of discontinuity. It is likely that a close study would reveal a band of disease along the coast from both sides of the Murray mouth. It must be remembered that a disease may be like a bush fire, with active burning at the fronts, and smouldering patches in the rear. We would not conclude from the discontinuous smouldering patches that the fire was moving by jumps. The most satisfactory evidence from which to conclude that "jumps" occurred would be the presence of the disease on both sides of a substantial barrier such as a desert or a sea; but no such evidence exists.

Pending sound evidence to the contrary, we may assume that myxomatosis spread by "creeping" along the rivers at about three miles per day from its initial introduction site near Echuca in May 1950.

My thanks are first owed to the various people of inland Australia whose observations and theories are the basis of this paper. Special thanks are due to Messrs. F. Jessup, M. Grey and B. Cameron, of the C.S.I.R.O., Mr. Mac Anderson, of the Pastoral Protection Board at Nyngan, and Mr. David Lee, of the School of Public Health and Tropical Medicine, Sydney.

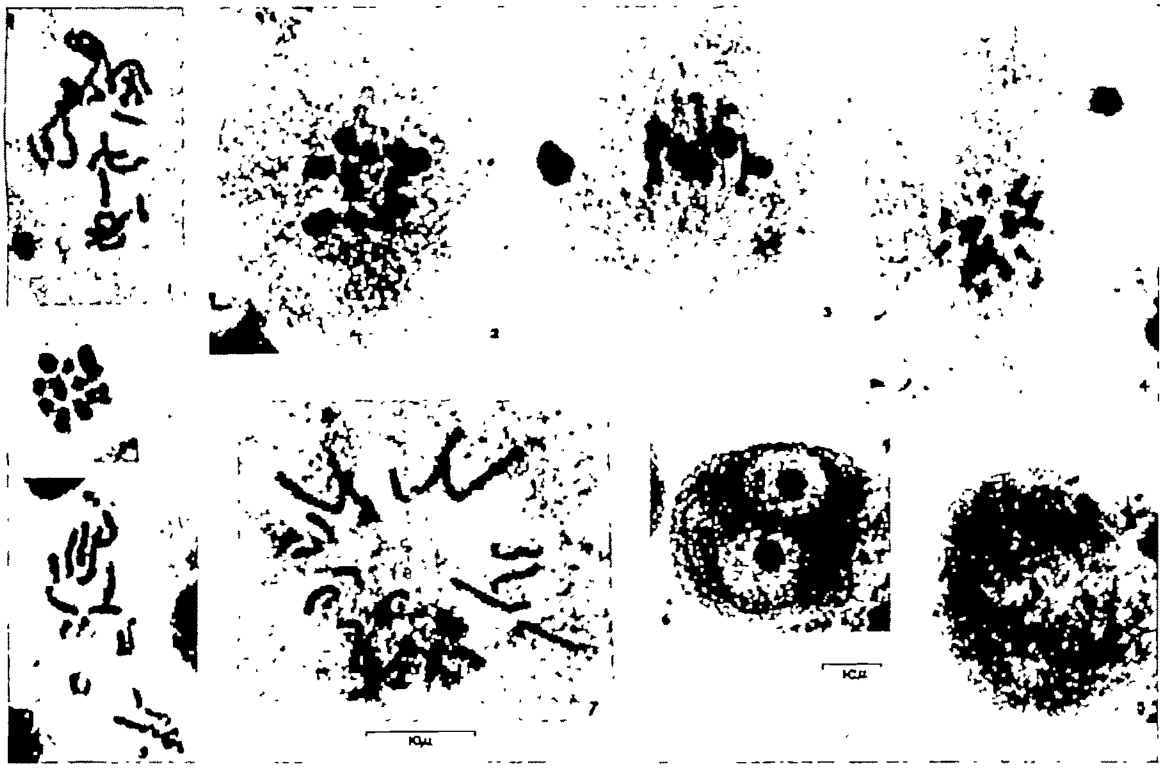
MATURATION AND PROBABLE GYNOGENESIS IN THE LIVER FLUKE, *FASCIOLA HEPATICA* L.

By Dr. ANN R. SANDERSON

Natural History Department, University of St. Andrews, University College, Dundee

RECENTLY when we happened to have a stock of living *Fasciola hepatica* in the laboratory, I made a few aceto-orcein squashes of the reproductive organs and was much impressed by the suitability of the material for demonstration work in cytology, for the following reasons: (1) from a single individual one can obtain an abundance of material for demonstration of maturation of both male and female gametes; (2) the chromosomes are large and can be counted even under a 2/3 objective; (3) the uterus contains capsules with eggs at different stages of maturation, and these, when removed and placed in water, continue their development right up to the emergence of the miracidia in about five weeks under laboratory conditions; (4) the material is available at all times of the year.

The diploid number of chromosomes is twenty, as clearly shown in early cleavage (Fig. 7), and similar



counts are readily obtained from spermatogonia (Fig. 9). First spermatocytes occur in rosettes of eight, and, in these, chiasmata are distinct in orcein squashes but show up best in Navashin-gentian-violet smear preparations. Ten bivalents are shown in Fig. 8. The ovary is relatively small, and oogonial plates are rather difficult to find since they occur singly and not in rosettes (Fig. 1). The egg is ectolecithal, and in aceto-orcein squashes the capsule bursts, usually around the cap, and the egg and yolk cells flow out in a flat sheet. The ooplasm is yolk-free and the maturation spindle is large and extends across the whole egg. The spindle is formed independently of the entrance of the sperm (Fig. 2) and appears to persist for a lengthy period. On entering the egg, the sperm swells up and stains faintly at first. Later it rounds off as a spongy mass outside the spindle area (Fig. 3). Despite careful search I have not seen any evidence of the formation of a male pronucleus. In examination of more than two thousand eggs of an age likely to be in first maturation division, I have found only four in which the chromosomes pass to telophase (Fig. 5). My impressions are that the bivalents fall apart (Fig. 4) and that later each set segregates around a nucleolus. I have not yet completed the investigation; but it appears that two equal-sized vesicular nuclei appear within the egg (Fig. 6). Later, after liberation of the capsule from the uterus, these fuse and give rise to a cleavage nucleus with two nucleoli. The first cleavage spindle in the now enlarged egg has the diploid number of chromosomes and gives rise to two unequal cells, each with two nucleoli. One of these is probably the propagatory cell found by Rees[1] in *Parorchis acanthus*. No polar body has been observed and the sperm nucleus seems to disappear in most cases before the fusion of the two vesicular nuclei. If my interpretation of these phenomena be correct, the fusion of the two nuclei is a method of regulation of the chromosome number, and the sperm does no more than activate. Gynogenesis has been recorded by Lepori[2], Benazzi-Lentati[3] and Benazzi[4] in free-living Turbellaria; but to the best of my knowledge it has not previously been recorded in the parasitic Trematoda.

Henneguy[5] investigated *Fasciola hepatica* and found neither polar body nor second maturation division in the egg. The paper by Schellenberg[6] was published when the rival theories of telosynapsis and parasynapsis were being hotly contested and when Janssens's observations on chiasmata were first made known. His illustrations agree fairly closely with my preparations; but his interpretation is obviously erroneous. He believed the diploid number to be 12, although he figured both nine and ten bivalents. I also have preparations of eggs showing nine bivalents; but in well-spread plates ten can clearly be seen. He endeavoured to explain discrepancies in number by a theory of late disjunction in some of the chromosomes; but, in my opinion, his difficulties arose on account of the prevailing method of preparation—by sectioning. His figures of the second division and of the polar body are far from convincing.

Although my Feulgen preparations are very clear, they yield no advantage over aceto-orcein squashes. In order to investigate further the fate of the sperm, it will be necessary to make some iron–hæmatoxylin preparations; but I would point out that Schellenberg used this stain yet failed to find any centrosome derived from the sperm nucleus.

Apart from the interest attached to the probable occurrence of gynogenesis, I feel that *Fasciola hepatica* is worthy of greater attention by cytologists. If gynogenesis should be proved to exist in the liver fluke, then I would suggest that other hermaphrodite animals should be further investigated, as the phenomenon may be more common than generally believed. [Jan. 10.

Note added to proof, June 5. Since this communication was submitted, an article on spermatogenesis in the liver fluke has been published by Mr. Bernard John[7], in which he states that the diploid chromosome number is twelve. If we are dealing with the same species, then the discrepancy must be due to the different methods of technique employed. Mr. John has used only sectioned material (Carnoy-iron hæmatoxylin). Cytologists to-day are generally agreed on the necessity for checking chromosome numbers by squash or smear methods. To obtain photographs where numbers are fairly high, the chromosomes must be well spread out to give a flat field. Over-much pressure on the coverslip may lead to broken chromosomes and an apparent higher number; but the number can be checked by careful drawing of more compact plates. In the fluke I have examined such plates stained by orcein, Delafield's hæmatoxylin and Feulgen in eggs in unbroken capsules. I have not used Carnoy as a fixative for *Fasciola*, but some years ago I sectioned material fixed in Navashin. I have re-examined this and feel obliged to state that for chromosome counts sectioned material compares unfavourably with squashed material.

'AFFINITY' IN MAIZE

DEVIATIONS from random segregation, analogous to those described in the mouse by Michie and Wallace[1], have been known for some time in maize. In view of the bearing such deviations from Mendel's second law, of independent segregation, may have upon the dynamics of chromosomes at meiosis, it appears useful to direct wider attention to what is known of the phenomenon in maize.

Affinity, which he termed 'false linkage', has been reported by Longley[2] to occur when there is preferential segregation at megasporogenesis of an abnormal type of chromosome 10[3]. This abnormal chromosome has a large, mainly heterochromatic, extra portion joined to the end of the long arm. In a plant heterozygous for abnormal 10 rather more than 70 per cent of the functional megaspores receive the abnormal chromosome, instead of the 50 per cent expected by chance. Rhoades[4] showed this was not due to competition between megaspores, of the kind found by Renner in *Oenothera*, but to a preferential segregation of the abnormal 10 to the chalazal megaspore. The degree of preferential segregation is affected by environmental factors.

Each of the ten chromosomes of maize may have one or more heterochromatic knobs which are visible during the pachytene stage of meiosis. The positions of particular knobs are characteristic, and their presence, or absence, is a character of the particular strain. Many strains have few knobs, or even none. The presence and absence of a particular knob on a chromosome, symbolized respectively as *K* and *k*, can be used, like two allelic genes, as genetic markers. Microscopic study of the progeny of a cross between a plant heterozygous for a particular knob and one which is knobless permits the detection of non-random segregation of the knob. Longley[2] found preferential segregation of the knob to the functional megaspore in knob heterozygotes, the preference being greatly accentuated if the plant was simultaneously heterozygous for the abnormal chromosome 10 (Table 1).

Table 1. PREFERENTIAL SEGREGATION OF KNOBBED CHROMOSOMES AT MEGASPOROGENESIS IN MAIZE: DATA OF LONGLEY[2]

Chromosome 10 constitution of parents	Chromosome 10 in megaspores	Knobbed chromosomes	Knobless chromosomes	Per cent knobbed	χ^2
$\frac{\text{Abnormal 10}}{\text{Normal 10}}$	Abnormal	616	302	67·1	107·4
	Normal	420	244	63·3	46·7
$\frac{\text{Normal 10}}{\text{Normal 10}}$	Normal	122	73	62·6	12·3

Preferential segregation was also observed in respect of some genes linked to knobs on chromosomes other than chromosome 10. Data are available for the *C*, *sh* and *wx* loci on chromosome 9 and for the *py* locus on chromosome 6. These data do not confirm the occurrence of preferential segregation in the absence of abnormal 10 which was suggested by the cytological data, but they do substantiate the occurrence of preferential segregation of knobbed chromosomes in the presence of abnormal 10. In the case of chromosome 9, the knob used was at the end of the short arm. All the test crosses had the dominant on the knobbed chromosome only, so the data contain no proper control by which the effects of viability differences on the estimate of preferential segregation can be readily eliminated. However, they do show (Table 2) effects large for the loci (*C* and *sh*) nearer to the knob and small for the locus (*wx*) farthest from the knob. The bias value is expected to be larger for the *C* locus than the *sh* locus; actually the observed value for the *C* locus is smaller, but not significantly so. The locus *wx* is close to the centromere of chromosome 9, and the order of value of the effects shows that the preference is occasioned by and from the knob. Any preferential segregation of the centromere and of genes in its neighbourhood is caused by the linkage of the centromere to the knob and not through the knob inducing a physiological change in the centromere, by which it exercises preferential orientation in the spindle. It is unknown

Table 2. PREFERENTIAL SEGREGATION IN MAIZE OF CHROMOSOME 9 GENES IN THE PRESENCE OF ABNORMAL CHROMOSOME 10; DATA OF LONGLEY[2]

Gene	Per cent recombination with knob	Per cent of megaspores with dominant gene		
		In presence of abnormal 10	In absence of abnormal 10	Difference*

Sh	26	65·71 ± 0·996	50·08 ± 1·47	15·63 ± 1·78
Wx	44	53·43 ± 0·316	51·01 ± 0·398	2·42 ± 0·508

Table 3. AFFINITY IN MAIZE; DATA OF LONGLEY[2]

F_1 genotype	Numbers of progeny *Py C*	*Py c*	*py C*	*py c*	Recombinations Number	Per cent
$\frac{Py\ K}{py\ k}$ $\frac{C\ K}{c\ k}$ $\frac{\text{Ab. 10}}{\text{Nor. 10}}$	1,119	461	488	218	949	41·51 ± 1·61
$\frac{Py\ K}{py\ k}$ $\frac{C\ K}{c\ k}$ $\frac{\text{Nor. 10}}{\text{Nor. 10}}$	731	775	773	740	1,548	50·00 ± 1·27

whether the effect occurs if abnormal 10 is homozygous.

The preferential segregation of the abnormal chromosome 10 does not influence the segregation of allelic genes if the chromosomes bearing them are knobless, nor does it influence segregation at microsporogenesis.

As a consequence of the preferential segregation described above, genes in different chromosomes, each heterozygous for knobs, segregating simultaneously in the same plant, show a similar, if not identical, phenomenon to the 'affinity' in segregation shown in the mouse. Data are given in Table 3 for coupling backcross progenies involving the pigmy (*py*) and coloured endosperm (*C*) loci.

In maize, the affinity depends upon heterozygosity for heterochromatic parts of the chromosome, the preferential, or polarized, segregation of which is activated, or accentuated, by the presence of a special chromosome, in this case the abnormal chromosome 10. The centromeres are not the active agents in maize, nor is there evidence for their being the agents in the mouse. Two possible mechanisms, not necessarily mutually exclusive, may underlie the promotion of affinity in maize by the abnormal chromosome 10. One may be an increase in the frequency of the non-homologous pairing which is shown by knobs at the pachytene stage of meiosis. The other is the formation of supernumerary centromeres, apparently in the neighbourhood of knobs, which occurs in the presence of the abnormal chromosome 10 at both divisions of meiosis[4].

D. G. CATCHESIDE

[4] Rhoades, M. M., and Vilkomerson, H., *Proc. Nat. Acad. Sci.*, 28, 433 (1942).

I AM grateful to Prof. Catcheside for directing attention to the observations in maize, and for affording me this opportunity of emphasizing an important distinction which I made in my previous communication[1] to which he refers. Of the two concepts which were differentiated under the names 'polar affinity' and 'mutual affinity', the former does little more than add an interpretative gloss to the phenomenon of 'polarized segregation' which has been described under that name by, for example, Catcheside[2]. It is the latter concept which is new, and it is the latter concept only—as can, I believe, be shown from our data[1]—which has application to the anomalous segregations observed in mice.

Now in the data of Longley[3] cited by Prof. Catcheside, polarized segregation involving 'knobbed' chromosomes, particularly chromosome 10, clearly occurs. It also appears that there may be an attraction (which it may seem reasonable to compare with 'mutual affinity') between the neo-centromeres of this chromosome and the neo-centromeres of other chromosomes—at least this seems to be one possible explanation of the enhancement of the polarized segregation of 'knobs' on other chromosomes (and of the attendant quasi-linkages) when abnormal 10 segregates to the preferred pole. Whether or not the term 'affinity' should in such a case be stretched to refer to neo-centromeres is discussed by Mrs. Wallace in the following communication.

I hope to publish a full treatment of these matters elsewhere.

DONALD MICHIE

Department of Zoology,
University College, London.

[1] *Nature*, 171, 26 (1953).

[2] *Ann. Bot.*, 8, 119 (1944).

[3] *Genetics*, 30, 100 (1945).

THE observations of Longley and Rhoades on the knobbed chromosomes of maize, to which Prof. Catcheside's letter has directed attention, were considered during the formation of my own views on the observations in mice for which Dr. Michie and I have used the term 'affinity'. There is a superficial resemblance between them in that they are both examples of non-random segregation, and both produce similar (although not identical) apparent linkages. That the same principle may, as Prof. Catcheside has implied, be found eventually to underlie them is possible, but certainly not yet proven. Indeed, a recent paper by Rhoades[1] gives a stronger indication of this probability than is mentioned by Prof. Catcheside, for Rhoades maintains that the centromeres *may*, in fact, be the active agents in maize (as theory proposes them to be in the mouse); he has shown that "the true centric region is involved in the formation of neo-centromeres", the latter occurring in the region of 'knobs'.

However, the resemblance is, at least at present, no more than superficial, for there are several important differences, both observational and theoretical, which make the use of identical terms undesirable.

Two observational differences are at once apparent from the published work. First, the anomaly in maize is confined to the sex in which the two poles of the dividing cell have a different biological destiny —it has been observed only in megasporogenesis, whereas the anomalous segregations have been observed in both males and females in the mouse. Secondly, the false linkages in maize depend on the presence of a particular chromosome (abnormal 10), which shows polar preference even in the absence of other abnormal chromosomes, whereas in the mouse no particular allele marking a point of attraction is known to be essential to the process or to have a polar preference. An important theoretical difference has already been mentioned: the maize phenomenon is thought to be controlled directly by the neo-centromeres and perhaps indirectly by the centromeres, whereas, in the absence of evidence for neo-centromeres in the mouse, the phenomenon here is thought to be controlled directly by the centromeres.

It would seem judicious, therefore, in order to avoid confusion, that separate terms be used for each phenomenon as a whole, namely, 'polarized segregation'—or, as Longley terms it, "preferential segregation"—and, on the other hand, 'affinity', until such time as their true relationship is fully understood. The term 'attraction' appears to be a sufficient description of the relation between neo-centromeres proposed as an explanation of Longley's data[2], as it is also for the relation between centromeres proposed in the mouse.

Electron Microscope Photographs of Polished Mineral Surfaces

Although the electron microscope has a wide range of applications in many branches of science, apparently it has not hitherto been used in ore microscopy for the study of opaque polished mineralogical surfaces. The instrument can be applied to great advantage, however, in revealing mineralogical structures and textures not visible with an optical microscope, and in throwing additional light on the complex problems of ore-deposition and the nature of ore-forming fluids.

The photographs reproduced here, taken with an electromagnetic transmission type of electron microscope, are of thin-film replicas prepared on polished surfaces of minerals and afterwards removed by a dry stripping process. In most cases it was found preferable to prepare the film on an electrolytically etched surface of the specimen, and to shadow the replicas before examination in the microscope. The maximum resolution obtainable using thin-film replicas is only of the order of 400 A., but even so this is about eight times as good as that of the best optical microscope.

Fig. 1. *Ex-solution particles of gold in cobaltite.* Replica obtained using a 0·75 per cent solution of 'Formvar' in chloroform; surface of specimen etched with equal amounts of 50 per cent CrO_3 and concentrated hydrochloric acid; immersion time, one minute; replica not shadowed; magnification, 3,600 diameters.

The gold particles are shown up in black; the small white circular spots represent holes in the thin-film replica. Two gold specks to the immediate right of the large patch are 0·36 μ and 0·29 μ, or 0·00036 mm. and 0·00029 mm., in diameter respectively. A thin veinlet of gold extends outwards from each side of the large gold particle. This photograph probably provides the first confirmation of the long-held belief that ex-solution products can exist in mineral specimens down to extremely small sizes, beyond the resolving power of optical microscopes. With the aid of the electron microscope it might well be possible to prove the presence of such inclusions at molecular sizes.

Fig. 2. *Ex-solution laths of cubanite in chalcopyrite.* Replica obtained using a 0·75 per cent solution of 'Formvar' in chloroform; mineral surface electrolytically etched, with 50 per cent phosphoric acid; current 3 amp., voltage 2·5; immersion time, 10 min.; replica shadowed using gold–manganin alloy; angle of shadowing approximately 30°; magnification, 3,600 diameters.

The cubanite laths are represented as dark bands in the surrounding lighter background of chalcopyrite. An intriguing feature of the chalcopyrite is the peculiar structure along its margins, which cannot be resolved with an optical microscope. It may be a form of strain structure induced in the chalcopyrite during segregation of the cubanite laths.

Figs. 3 and 4. *Ex-solution lamellæ of ilmenite in magnetite.* Replica obtained using a 2 per cent solution of collodion; surface of specimen not etched; replica shadowed using gold–palladium alloy; angle of shadowing approximately 30°; magnification, 3,800 diameters.

In this case photographs with good contrast have been obtained from an unetched surface, despite the fact that ilmenite and magnetite are so similar in hardness. They illustrate that the ilmenite lamellæ, which under an optical microscope appear to have perfectly straight edges and smooth surfaces, actually have irregular margins and a fine surface structure. This surface structure on the ilmenite laths cannot yet be explained.

I wish to thank Dr. H. Wilman, of the Applied Physical Chemistry Laboratories at this College, for generously providing laboratory facilities, and in particular Mr. H. I. Matthews for his help and advice, without which this work would not have

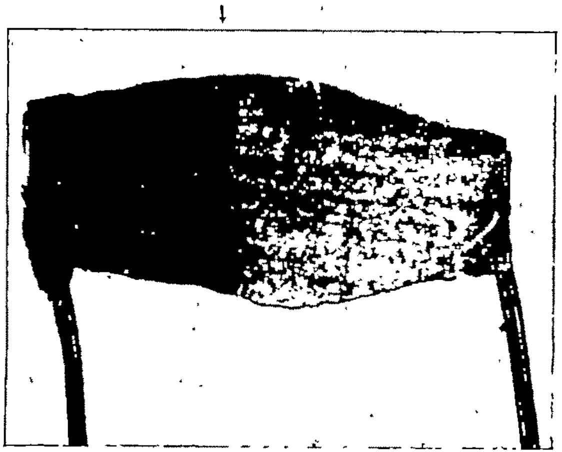
p-n Junction revealed by Electrolytic Etching

In the preparation and application of *p-n* junctions in germanium and similar materials, it is often important to locate the potential barrier precisely in order to attach electrodes or probes near by. Such a barrier is, in general, not visible, as the crystalline structure of the material on either side of it is identical, that is, a single crystal of germanium of high purity and with a high degree of perfection throughout. The fact that one part (the *n*-type region) conducts by electrons in the conduction band and the other (the *p*-type) in the valency band, that is, by 'holes', cannot be shown up by any of the standard metallographic techniques. The usual method of locating the barrier, namely, by electrical probing along the surface, is not very satisfactory.

However, the boundary can be shown up by using a method that depends on the rectifying behaviour of such a junction. The specimen is immersed in a suitable electrolyte, and electrical current is forced through it in such a way that only the *n*-region is anodically attacked, that is, the positive terminal of a battery is connected to the *n*-part of the specimen and the negative to an inert electrode, such as graphite, nickel, stainless steel, etc., serving as the cathode. Regarded as a rectifier, the junction is then biased in the blocking direction. The current flowing into the specimen cannot cross the barrier but passes into the electrolyte instead, and from there to the cathode. The *n*-type part of the specimen is therefore etched anodically, while the *p*-type part of the sample, passing practically no current, is scarcely attacked.

In some preliminary experiments, 10 per cent potassium hydroxide aqueous solution was used as the electrolyte, at a temperature of about 25° C. The best results were obtained with the specimen ground in the usual way, without any prior etching being applied. A current density of about 1 m.amp./mm.^{2} was maintained for 1–2 min. and was found to give quite distinct etching, as shown in the photograph.



p-n Junction (marked by arrow) in germanium

Various alternatives of the method can be used. Instead of using an independent (inert) cathode, the D.C. supply voltage may be applied directly across the two ends of the specimen, the anode to the *n*-part as before and the cathode to the *p*-part. Current passing into the *n*-part from the anode again cannot cross the junction barrier, but instead passes into the electrolyte and thence into the *p*-part of the specimen. There is practically no effect on that part of the germanium specimen acting as the cathode, while the *n*-part will be etched anodically as before. The leads connecting the specimen to the voltage supply should be insulated to avoid corrosion.

In a similar way, an *n-p-n* specimen can be made to show up the *p*-region; if connected with the two *n*-parts joined in parallel, these will be etched anodically, while the *p*-part will remain unaffected, practically no current passing through its surface; the cathode in this case should be a neutral material, for example, graphite.

It was noted that the electrolytic type of etching, while rendering the *p-n* boundary readily visible, is much less effective than certain chemical etches are in improving the rectifying characteristics of a junction. This is presumably because only a strong chemical etch will strip the junction completely of any contaminated surface layer which might otherwise act as a partial short-circuit in parallel with the high electrical resistance of the barrier. Electrolytic etching as described will only clear the *n*-part of the junction; if the *p*-part were used as cathode, electrolytic etching might make matters worse by cathodic deposition on the *p*-region close to the junction. The following rectification ratios were obtained on a particular junction after various treatments.

Treatment of junction	Surface ground	Electrolytic etch (*p*-part as cathode)	Electrolytic etch (independent cathode)	Chemical etch *C.P.4*
Rectification ratio	1 : 2	1 : 2·8	1 : 45	1 : 10,000

We wish to express our gratitude to E. W. R. Francis, who carried out most of the experimental work.

Since starting these experiments, it has come to our notice that similar techniques are being developed elsewhere in Britain and the United States.

Travelling Disturbances in the Ionosphere

Measurements of the horizontal velocity of travelling disturbances in the *F*2 region of the ionosphere have been made in this department over the past three years, using the method described by Munro[1]. Constant-frequency pulse transmitters were set up at the base station in the Physics Department of the University of Western Australia, and at two other stations situated respectively 15 miles east and 25 miles south-east. The two remote stations were triggered, after a short adjustable delay, by the

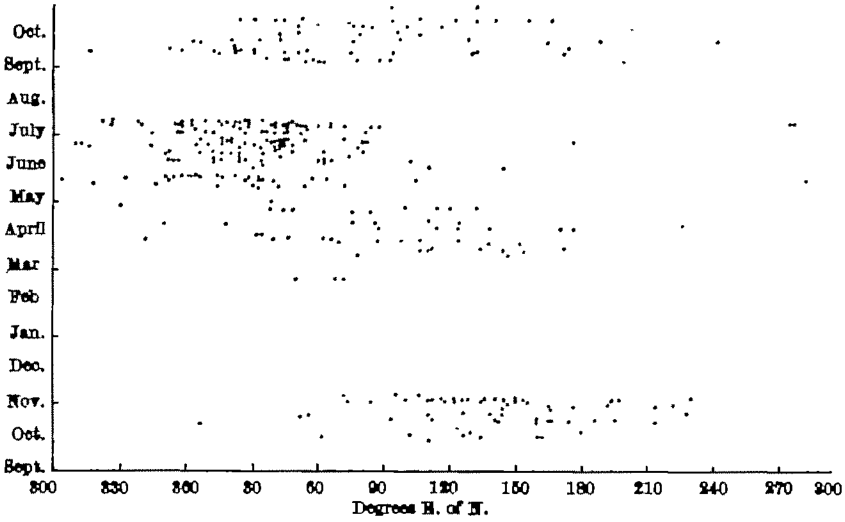

Fig. 1

ground wave from the University transmitter. Three sets of echoes were obtained at the base station, one reflected vertically from overhead and the other two at oblique incidence from the mid-points between the remote stations and the base. They were recorded on the one film by the conventional techniques. The frequency used was 5·8 Mc./s. and the pulses were 100 μsec. long with a pulse repetition frequency of 40 c.p.s.

It was found that changes in the reflecting layer occurred at different times at the three reflexion points, and the velocity of motion of these disturbances could be determined. These time differences occurred in nearly all disturbances of the reflecting layer, for example, peaks and dips of virtual height, splitting of ordinary and extraordinary rays; but discontinuities in the recorded trace, called "*Z*'s" by Munro, proved to be the most reliable.

The directions determined over the year are shown in Fig. 1. It was not possible to keep the system in continuous operation; but Munro's results show that, in Sydney, the directions are substantially constant during the non-recording periods in Perth.

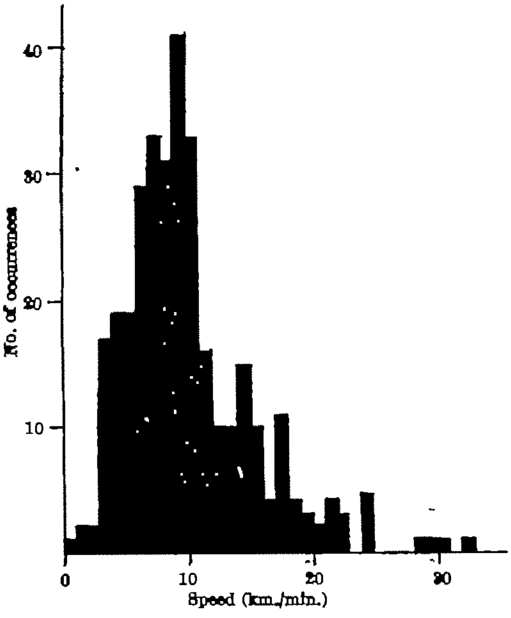

Fig. 2

The direction of travel in summer lies between 90° and 180° E. of N. and in winter between 0° and 60° E. of N. with a rapid change-over occurring in the equinoxial months (see Fig. 1). Variations between the two conditions occur; but the change from one set of conditions to the other is accomplished in a day. Fluctuations of up to 50° occur quite commonly during the day, and even larger ones have been noted. The speed has been found to vary from 5 to 20 km./min. with a maximum of occurrence at 10 km./min. (see Fig. 2); but no regular variation has been noticed.

The speeds (and also the number of *Z*'s per day) were compared with auroræ and the weather; but no correlation was obtained.

Another phenomenon that has been noted on the records is a quasi-periodic rise and fall of the virtual height. It is thought that this variation arises from the same meteorological source as the *Z*'s. The velocities determined agree quite well in direction with those determined from *Z*'s, but the speeds are generally much larger. These apparently greater speeds may be due to the method of analysis of the records.

The values of velocity obtained agree quite closely with those reported by Munro in Sydney, and it seems that the velocities are substantially constant for 2,000 miles[2].

A more detailed account of this work is in course of preparation and will be published elsewhere. I acknowledge the assistance given by the Radio Research Board, particularly by Dr. G. H. Munro.

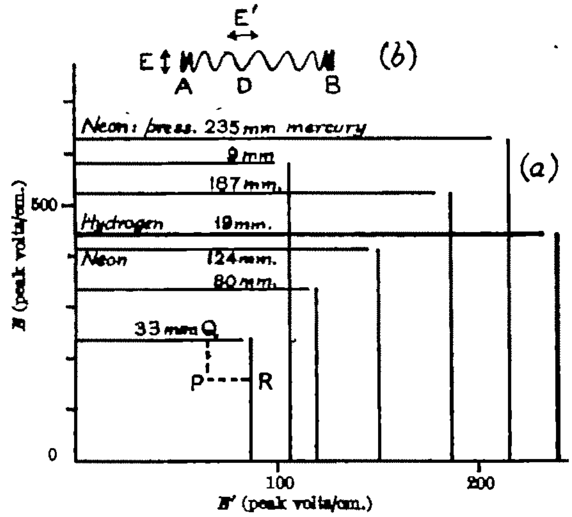
Breakdown of a Gas subject to Crossed Electric Fields

In microwave breakdown of a gas, the amplitude of drift movement of an electron is small except at very low pressures, and the hypothesis has been made that the return of an electron over its previous track may help to initiate the discharge[1]. The experiments now reported deal with an attempt to convert the simple to-and-fro drift movement into a zig-zag movement, and to examine the effects of this on the stresses required to initiate breakdown.

The gas under examination was confined in a glass vessel inside a cylindrical resonator energized by repeated 1-μsec. pulses at a frequency of 10,000 Mc./sec. In the resonator, the electric component *E* of the field pattern set up consisted of a closed ring



(a) Typical conditions of breakdown in combined fields. Thick line, hydrogen; frequency of auxiliary field, 10 Mc./sec. Thin lines, neon; frequency of auxiliary field, 3·06 Mc./sec.

(b) Illustrating the movement of an electron in the combined fields: relative amplitude exaggerated in the E direction

of electric force in a plane perpendicular to the axis of the cylinder ($H011$ mode), the intensity falling off towards the resonator walls and towards the centre. In this mode, the wall currents are circumferential and so the ends of the resonator could be insulated from the cylindrical walls, making it possible to apply an auxiliary field E' in a direction generally parallel to the axis of the resonator. Steady fields so applied caused an increase in the microwave stress required to produce breakdown in air, hydrogen and neon, but the results are ambiguous in that the increase could alternatively be attributed to gross movement of the electrons and ions towards the walls of the containing vessel. Accordingly, alternating auxiliary fields were applied instead of unidirectional fields, at frequencies of 1, 3 and 10 Mc./sec., with results shown in Fig. a for a typical case.

Starting from conditions represented by a point such as P, on increasing the microwave field no breakdown occurred until the conditions at Q were obtained. Similarly, on increasing instead the 3-Mc./sec. field, no breakdown occurred until the conditions at R were obtained. It appears that the two fields act independently in producing breakdown, as shown by the rectangular form of the curves.

A partial explanation is as follows. The field of lower frequency is continuously applied and so the vertical lines may simply represent breakdown occurring in the intervals between the microwave pulses. If it be assumed that breakdown by the microwave field is facilitated by the return of the electron along its track, then breakdown will begin at A or B (Fig. b) and the results agree with the view that at D the breakdown stress is increased by the auxiliary field. This is supported by the observation that the statistical lag before breakdown increases with increasing values of E'. The surprising feature is the complete failure of the auxiliary field to help microwave breakdown, even when its value is only a little below that at which it could by itself initiate the discharge.

Grateful acknowledgments are made to the Department of Scientific and Industrial Research for a maintenance grant (P. E. L.), to the British Electrical and Allied Industries Research Association for a grant for apparatus and to the Director of that Association for permission to publish this communication.

Variation of the Incompressibility of an Elastic Material subjected to Large Hydrostatic Pressure

Birch[1], using Murnaghan's finite elasticity theory, has shown that, at pressures existing in the earth's interior, the gradient of the incompressibility k, with respect to the pressure p, is a decreasing function of pressure. This communication reproduces the main features of Birch's results but, by starting from a later derivation of Murnaghan, it is found possible to obtain two useful formulæ for the calculation of k and dk/dp at large pressures.

In the course of his theory, Murnaghan[2] derives the formula:

$$\frac{d(\lambda + \frac{2}{3}\mu)}{dp} = \frac{\frac{2}{3}(\lambda + \frac{2}{3}\mu) - B + \frac{1}{3}p}{\lambda + \frac{2}{3}\mu + \frac{1}{3}p} \qquad (1)$$

where $k = \lambda + \frac{2}{3}\mu + \frac{1}{3}p$. B, a possible function of pressure, is a combination of second-order elastic parameters. It is impossible to obtain an exact solution of (1) without knowledge of the variation of B with pressure, but a solution can be obtained by assuming B to be an absolute constant. With this restriction, equation (1) can now be solved exactly, but the solution is unwieldy. In order to obtain a useful solution, we take $\lambda + \frac{2}{3}\mu$ in the second member of (1) equal to its value k_0 at zero pressure. Thus we obtain:

$$\frac{dk}{dp} = \frac{k_0 - B + 4p/9}{k_0 + p/3}, \qquad (2)$$

which yields the solution:

$$k = k_0 + 4p/3 - (k_0 + 3B) \log (1 + p/3k_0). \qquad (3)$$

Towards solving equation (1) we have, in effect, taken the elastic parameters $\lambda + \frac{2}{3}\mu$ and B in the second member equal to their values at zero pressure. This implies that the approximate results (2) and (3) will not be valid for very large pressures, but no great discrepancy should be involved in the range of pressures occurring in the earth's interior.

The studies of the earth's interior have shown that the following values are at least correct to one significant figure:

$k_0 = 2 \times 10^{12}$ dynes/sq. cm.;
$k = k_0 + 4p$, where p is not too large;
$p_c = 2k_0$, where p_c is the pressure at the centre of the earth.

Using the result $dk/dp = 4$ where $p = 0$, we find from equation (2) that $B = -3k_0$, so that equations (2) and (3) become:

$$\frac{dk}{dp} = \frac{4k_0 + 4p/9}{k_0 + p/3}, \tag{4}$$

$$k = k_0 + 4p/3 + 8k_0 \log (1 + p/3k_0). \tag{5}$$

With equations (4) and (5) and the assumed values for the earth's interior, we can now construct the accompanying table, where the units of p and k are 10^{12} dynes/cm.

p	dk/dp	k	Depth
0	4	2	0
1	3·62	5·8	2,200 km.
2	3·33	9·3	3,500 km.
3	3·11	12·5	4,800 km.
4	2·93	15·5	centre

In the construction of this table, the assumption of Bullen's compressibility pressure hypothesis is implicit, and his values giving the variation of pressure with depth have been used to estimate the approximate depth. It will be noticed that there is a very good correspondence between the values of k obtained from equation (5) and Bullen's[3] values.

I wish to thank Prof. K. E. Bullen, of the University of Sydney, and Prof. G. Bosson, of the N.S.W. University of Technology, for their interest and assistance.

An Extended Smith–Lagrange Invariant

IT is well known in optics that, if μ_r is the refractive index of the rth medium of a co-axial system, h_r is the height of the image of a given object from the axis in the same medium, and α_r is the angle a selected ray makes with the axis at the image plane, then

$$\mu_r h_r \left\{ \begin{matrix} \sin \alpha_r \\ \tan \alpha_r \end{matrix} \right. \tag{1}$$

is invariant (Smith–Lagrange invariant). The choice of $\sin \alpha_r$ or $\tan \alpha_r$ varies with different authors. The relation holds in all systems where $\sin \alpha$ and $\tan \alpha$ are indistinguishable.

The development of various two-stage processes of image formation[1], in which the wave-length may be altered between object and image, makes it profitable to consider whether the wave-length can be introduced. Since wave-length is inversely proportional to refractive index, the form:

$$\frac{\mu_r h_r \sin \alpha}{\lambda_r} \tag{2}$$

as invariant suggests itself. It is readily verified in the case of diffraction microscopy that this is correct.

Hopkins[2] has recently published a coherence criterion for a beam of circular cross-section:

$$\frac{\mu h \sin \alpha}{\lambda} = \frac{z}{2\pi} \not> 0{\cdot}16, \tag{3}$$

in which h and $\sin \alpha$ are capable of two alternative interpretations, one of which agrees with that of (1) and (2). Comparison with (2) shows at once that, if a beam is coherent in one image plane of a Gaussian co-axial system, it will be coherent in all other image planes. Thus coherence is conserved in such systems. Moreover, if the invariant (2) exceeds 0·16 in numerical magnitude, the degree of partial coherence has been shown by Hopkins to be $2J_1(z)/z$, and is still invariant down the system, though now imperfect.

The Smith–Lagrange invariant thus corresponds to the physical law that the degree of coherence is conserved from image plane to image plane in Gaussian systems.

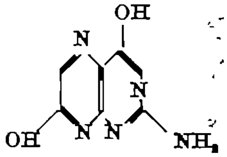
*Iso*xanthopterin

WE have recently prepared *iso*xanthopterin (2-amino-4 : 7-dihydroxypteridine) by a new synthesis, namely, the condensation of triamino-4-hydroxypyrimidine with ethyl glyoxylate hemiacetal. The synthesis, purification and analysis will be reported in detail elsewhere. The ultra-violet spectrum of the product consisted of three peaks at the $\lambda_{max.}$ values previously reported[1,2], but the extinction coefficients were so much higher as to suggest that the samples previously examined contained no more than 80 per cent of *iso*xanthopterin. Our results are as follows (material dried at 150°, analysing as anhydrous, dissolved in 0·1 N potassium hydroxide).

$\lambda_{max.}$ (mμ)	ε	$\log \varepsilon$
339	14,200	4·15
254	11,550	4·06
223	(38,000)	(4·58)



The ε at 223 mμ may be subject to a small error from stray light.

We wish to thank Dr. E. R. Holiday, of the Medical Research Council Spectrographic Research Unit, London Hospital, and Dr. F. Korte, of the Biochemische Abteilung, Chemisches Staatsinstitut of the University of Hamburg, for confirming the above spectrographic results, using our synthetic material. Dr. Korte tells us that previous spectra have been obtained only from material of natural origin.

Effect of Ultra-violet Light on Deoxyribonucleic Acid in Rat Thymocytes

The amount of deoxyribonucleic acid recovered from ultra-violet light irradiated intact rat thymocytes has been found to be significantly less than the amount recovered from non-irradiated controls. The thymus glands of twenty normal 150-gm. Wistar-strain male rats were removed immediately after decapitation of the animals, placed in 140 ml. of Ringer's solution and homogenized for 30 sec. in a Waring blendor. The resultant suspension of thymocytes was removed to a dark-room and divided into two equal portions, one of which served as a control. The other was placed in an 30-ml. quartz-bottom van Tieghem cell. While being constantly agitated by a slowly rotating stirrer, in order to ensure uniform exposure of all the cells, the suspension was irradiated from below for 30 min. with ultra-violet light ($3 \cdot 4 \times 10^6$ ergs). The ultra-violet source, used without filters, was an air-cooled, quartz-spiral mercury resonance lamp (Hanovia), which, according to a Hanovia ultra-violet meter, Model *AV* 971, emits about 25 per cent of the total output in the ultra-violet below λ = 2800 A. The irradiated and control suspensions were left in the dark-room to avoid possible side effects due to photo-reactivation. A period of 5½ hr. was allowed to elapse before extraction of deoxyribonucleic acid, in order to provide sufficient time for possible depolymerization of the acid induced by the radiation. Thymocyte viability for a period of 5½ hr. after homogenization and irradiation was verified by means of tissue culture. Deoxyribonucleic acid was extracted according to the Limperos modification[1] of the Mirsky–Pollister method[2], dissolved in distilled water and then lyophilized. The weight of deoxyribonucleic acid obtained from irradiated tissue homogenates (seven replicate experiments) was only 52·9 per cent ($\text{S.E.}_{\text{mean}}$ 4·6) of the weight of that obtained from the non-irradiated controls. Nitrogen and phosphorus content were determined on aliquot portions made up on the basis of percentage weight of deoxyribonucleic acid. Adjustment to equal concentrations of the acid was based on phosphorus content. No appreciable differences between irradiated and control samples were found in relative viscosities, structural viscosities, or sedimentation rates.

Thymine was determined according to the method of Day[3] on the supernatant fluids (Ringer's solution and the 0·14 *M* saline extraction fluids) collected during the initial stages of the extraction process. The greater proportion of loss of deoxyribonucleic acid calculated on the basis of thymine content of the supernatant fluids from the irradiated tissue homogenates occurred during the 5½ hr. period following irradiation before the extraction of deoxyribonucleic acid.

Depolymerization of deoxyribonucleic acid *in vitro* by prolonged exposure to ultra-violet radiation was demonstrated by Hollaender *et al.*[4]. A fall in nuclear absorption of mouse lymphocytes, thymocytes and stem cells of bone marrow during such irradiation was reported by Bradfield[5] and was suggested by him to be due to depolymerization of the acid with immediate extranuclear leakage of the acid breakdown products.

The small amount of deoxyribonucleic acid recovered from irradiated tissue homogenates and the large amount of thymine present in the Ringer's supernatant fluids indicate that, as a result of ultra-violet irradiation, partial fragmentation of the polymerized deoxyribonucleic acid molecule occurred. Since no appreciable differences were found between the physico-chemical characteristics of the deoxyribonucleic acid recovered from the controls and from the irradiated homogenates, apparently not all the deoxyribonucleic acid in the irradiated homogenates was depolymerized. There was a slight loss of the deoxyribonucleic acid from the controls attributable to mechanical injury. The major loss of the acid from the irradiated homogenates, however, must have been due to ultra-violet radiation.

Deoxyribonucleic Acid Content of the Cell Nucleus and Mitosis

The fact that the deoxyribonucleic acid content in the nuclei of a given tissue remains constant at least between certain limits suggests that mitosis must necessarily be preceded, accompanied or followed by a synthesis of deoxyribonucleic acid. The moment of this synthesis is still under discussion.

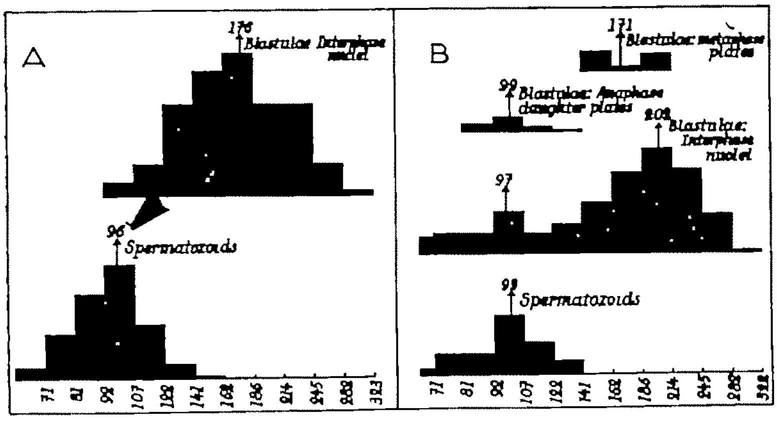
The blastula of *Artemia salina* L. was chosen as material for the study of the problem. At the moment of the invasion of the blastocoel by the yolk granules[1] the nuclei remain near the surface of the germ and present semi-synchronous divisions, so that blastulæ practically devoid of mitosis and others with numerous nuclear divisions are easily found. After telophase, most of the newly formed nuclei can be recognized by their volume. The two little nuclei swell progressively during early interphase to the volume of the interphase nuclei.

It seemed to us that a comparison between the amount of deoxyribonucleic acid in nuclei of blastulæ devoid of mitoses and those with numerous mitoses could give some information upon the deoxyribonucleic acid content during nuclear division. The histochemical method of L. Lison[2] was used for this purpose. The calculated mean optical density of the nucleus multiplied by its surface gives the amount of deoxyribonucleic acid expressed in arbitrary units. The reported figures have only relative values. Those brought together in each of the histograms (*A*, *B*) correspond with nuclei found in sections of a female fixed *in toto* (alcohol 9, formalin 1), which were brought on to the same slide to ensure a uniform Feulgen reaction. In the histograms the relative amounts of deoxyribonucleic acid are plotted logarithmically as abscissæ and the relative frequencies of the classes comprised between two successive figures of the horizontal scale are plotted as ordinates. As reference, the spermatozoids abundantly present in the general cavity of the females were measured.

In histogram *A* the mean deoxyribonucleic acid content of the (haploid) spermatozoids obtained by 110 measurements corresponds to 96 arbitrary units. The contents of nuclei contained in six blastulæ devoid of mitoses vary between wide limits. Those variations are in no way connected with those of the nuclear dimensions and forms. The existence of a definite frequency maximum enables us to calculate a mean value from the 215 measurements. This value (176 arbitrary units) was found, as expected for those diploid nuclei, to be nearly twice the content of the spermatozoids.

Histogram *B* summarizes the results obtained from five blastulæ which contain numerous mitoses. The mean deoxyribonucleic acid content of the spermatozoids found in the sections on the same slide, as calculated from fifty measurements, corresponds to 99 arbitrary units. Nearly 160 interphase nuclei were measured. The histogram shows clearly two frequency maxima. The most important (202 units) is situated very close to the theoretical diploid value (198 units); the other (97 units) corresponds practically to half this value. By measurement of nuclei chosen at random, it is clear that the nuclei with a low figure contain only about one-fourth of the total number of the interphase nuclei. When there is no trace of this group in the blastulæ devoid of mitoses (histogram *A*) it seems clear that its appearance is related with the presence of mitoses. This is confirmed by the fact that the small post-telophasic nuclei and most of the swelling nuclei belong to this group. Fifteen metaphase plates were also measured. Notwithstanding the small number of measurements and the low values caused by the extreme condensation of chromatin, the values obtained correspond quite well to the diploid group. The eleven measured daughter plates at anaphase present a frequency maximum which is exactly half the 'diploid' amount.

These results show clearly that, in our material, synthesis of deoxyribonucleic acid does not occur during either prophase or metaphase, but at the beginning of interphase, before, during or after the swelling of the nucleus. Thus they are comparable with the results of J. Pasteels and L. Lison[3], using different material, for deoxyribonucleic acid synthesis during telophase. Other investigators[4,5] on different materials have found deoxyribonucleic acid synthesis to twice the 'diploid' value before or at the beginning of mitosis, so that the 'diploid'-amount is re-obtained after the disjunction of the chromosomes.



These discrepancies show clearly that more investigations on the most varied materials are necessary and that it is too soon to draw general conclusions on this problem.

This work was assisted by a grant from the Belgian National Foundation for Scientific Research.

Intracellular Distribution of Vitamin A Esterase Activity in Rat Liver

In 1949, Ganguly[1] observed the presence of an enzyme in pig pancreas capable of hydrolysing vitamin A ester. Recently, McGugan and Laughland[2] have demonstrated vitamin A esterase activity in rat-liver homogenates. Observations in this laboratory fully confirm this report, and show that the activity is located in the microsomal fraction of the homogenate.

Male rats of the University of Southern California strain, raised on a vitamin A - free diet[3], and receiving 15–20 I.U. of vitamin A per week, were sacrificed under light nembutal anæsthesia by direct heart puncture. The residual blood in the liver was removed by perfusion with isotonic saline solution. The excised liver was homogenized in 0·25 *M* sucrose solution by means of the Potter–Elvehjem homogenizer[4], and the homogenate was fractionated by differential centrifugation[5]. All fractions and the whole homogenate were suitably diluted with 0·25 *M* sucrose solution so as to yield equivalents of 200 mgm. of original liver tissue per ml.

Crystalline vitamin A acetate, dissolved in *n*-hexane, was chromatographed through alumina to remove any free vitamin A. A dispersion of the acetate was made in water as described by McGugan and Laughland[2]. Incubation and extraction were carried out according to their method, and the vitamin A ester and alcohol were separated and determined as described by Ganguly and associates[6].

Preliminary experiments demonstrate that the activity is quantitatively present in the microsomal fraction, and that the nuclear, mitochondrial and supernatant fractions are inactive. Omachi and co-workers[7] reported the presence of an esterase (with methyl butyrate as substrate) in the microsomal fraction. Further work to determine the specificity of this enzymatic hydrolysis of vitamin A ester is in progress, and full details will be published elsewhere.

We gratefully acknowledge the support of the Nutrition Foundation, Inc., in the form of a research grant, as well as a gift of vitamin A acetate from Dr. P. L. Harris, of Distillation Products, Inc.

Assay of Thyroid-stimulating Hormone, Thyroid and Thyroid-like Substances on *Xenopus* Tadpoles

IN 1941, Landgrebe and Purser[1] showed that larvæ of *Xenopus lævis* can be obtained in the laboratory all the year round, and suggested that they could be used for assay of thyroid and thyroid stimulating hormone. In 1945[2], Deanesly and Parkes published a method for assay of thyroid-like activities by oral administration, using these tadpoles at an early stage. Such animals, however, vary a great deal in sensitivity and are too small for satisfactory injection and operative surgery. In the past few years, the anatomy, feeding mechanism, growth, food requirements, development and metamorphosis of the larvæ have been thoroughly investigated. Methods for routine thyroidectomy and injection of extracts have been worked out using larger tadpoles. Methods of husbandry have been devised which reduce individual variation to a minimum, and produce large metamorphically retarded larvæ suitable for assay work (c. 400 mgm. with length of hind leg c. 0·3 cm.).

Onset and progress of metamorphosis depend upon the amount of active iodine ingested by the larva in its food. Different foods vary widely in their content of active iodine; for example, eight batches of commercial liver powder produce emergence of front limb in similar batches of larvæ in times varying between nine days and more than 105 days.

Several workers, notably Gaddum[3], used larvæ of *Rana temporaria* for assaying iodinated substances by oral administration. Much of this work has been repeated using *Xenopus* larvæ. Sodium thyroxine can be measured in concentrations in the water as low as 3×10^{-9}, and *Xenopus* larva, with its efficient filter-feeding mechanism[4], is an ideal test animal for assays by oral administration.

We have concentrated, however, on a micro-injection technique for the assay of thyroid-like substances and thyrotrophic hormone. Very small volumes of the solutions under test are required, and the method can be used for investigating body fluids. D'Angelo *et al.*[5] and Reineke and Turner[6] used an intraperitoneal injection route in the larvæ of *Rana pipiens*. In *Xenopus* larvæ it is better to inject into the submental lymph space using the inter-hyoideus muscle as a seal. Up to 0·02 ml. of the substance under test may be given.

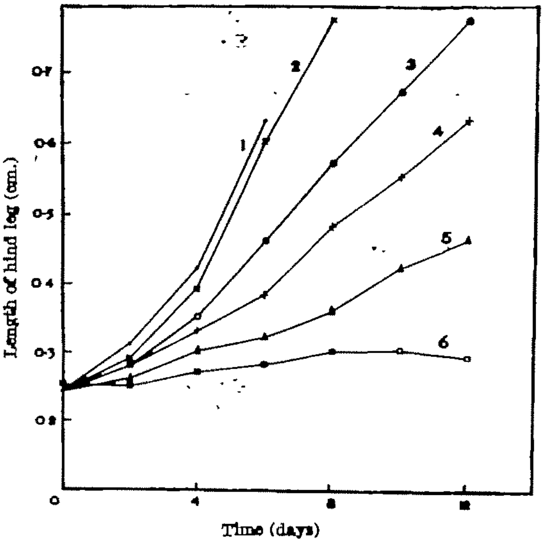

Fig. 1. (1) 0·05 μgm. sodium thyroxine every two days
(2) 0·025 " " " " " "
(3) 0·01 " " " " " "
(4) 0·005 " " " " " "
(5) 0·001 " " " " " "
(6) 0·01 ml. *Xenopus* saline

The effect of different doses of sodium thyroxine on hind leg growth is shown in Fig. 1. Using groups of ten larvæ, amounts of sodium thyroxine as small as 0·004 μgm. in four doses of 0·001 μgm. each in 0·01 ml. *Xenopus* saline can be estimated.

D'Angelo *et al.* used larvæ of *Rana pipiens* for assay of thyrotrophic hormone. They measured the effect on the follicular epithelium of thyroid glands of 'stasis' (starved, non-metamorphosing) larvæ. This method can be used with *Xenopus* larvæ. Fig. 2*b* shows a photomicrograph of a section of the thyroid gland of a *Xenopus* larva which had been starved for two weeks. Fig. 2*c* shows the effect on such a gland produced by human serum from a thyrotoxicosic patient. The follicular epithelium is greatly stimulated, and increase in cell height can be used as a criterion.

We have developed a non-histological method which involves thyroidectomy, a relatively easy

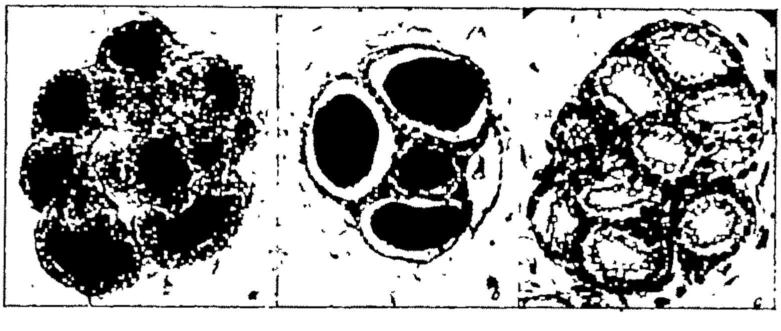

Fig. 2. Transverse sections of thyroid gland of *Xenopus* larva

(*b*) Gland of larva starved 14 days. Stained hæmatoxylin (Heidenhain). × 180
(*c*) Gland of starved larva after injection of serum from thyrotoxicosic patient. Stained hæmatoxylin (Ehrlich) and eosin. × 250

operation in the transparent *Xenopus* larva. Injection of thyrotrophic hormone increases the rate of hind-leg growth in normal animals with little effect in thyroidectomized animals. Some batches of purified thyrotrophic hormone seem to be contaminated with iodinated substances. However, the method can be used for assay of the extracts, whether active iodine is present or not, by using both normal and thyroidectomized larvæ.

Similarly, thyroid hormone and thyrotrophic hormone, present in human blood and body fluids of other animals, are effective and can be estimated. Work continues on the thyroid and thyrotrophic hormone content of human blood, which may differentiate cases of hyperthyroidism.

We are greatly indebted to Messrs. Armour, of Chicago, and to Organon, Ltd., for supplies of thyrotrophic hormone.

Isolation of a New Strain of *Plasmodium knowlesi*

Sinton and Mulligan[1] isolated a virulent strain of *Plasmodium knowlesi* from a mixed infection of *P. knowlesi* and *P. cynomolgi* in *M. irus* monkeys imported into Calcutta from Singapore; it was possible only after rapid serial passages through rhesus (*M. rhesus*) monkeys. Eventually, the strain of *P. knowlesi* was being maintained for chemotherapeutic and other studies by the Malaria Institute of India, Delhi, and by some laboratories in Great Britain and the United States.

By 1952, these institutions had either completely lost the strain or it was found to be attenuated, as reported by Jaswant Singh, Ray and Nair[2]. Attempts have been made in recent years to isolate again a virulent strain in rhesus monkeys from *M. irus* from Malaya, through the courtesy of the Institute for Medical Research, Federated Malay States. From the materials received, only *P. cynomolgi* and *P. inui* could be demonstrated[3].

Early this year, Dr. Edeson was able to detect a plasmodium which he believed to be *P. knowlesi* in a Kra monkey (*M. irus*) obtained from the Nuri Valley near Tampin (Malaya). When the infection was passaged to rhesus monkeys sent from the Malaria Institute of India, the intensity and course of infection were found to be severe. Samples of blood from two such rhesus monkeys were flown to Delhi in January 1953, and rapid serial passages were made. Inoculations were given intravenously or intraperitoneally, the dose of inoculum varying from 1×10^6 to 50×10^6. The prepatent period varied from one to three days when infected blood was injected intraperitoneally, and from four hours to forty-eight hours after intravenous injection. When patency was fully established, irrespective of the dose of inoculum and the route of injection, in all cases there was rapid rise in parasite counts. In most cases it reached 90–96 per cent cell infection prior to death, which invariably occurred five to seven days after the appearance of parasites in the peripheral circulation. Of fifty animals studied, hæmoglobinuria was observed in about ten. Extreme anæmia and rapid prostration were dominant features in all cases.

Differential parasite counts[4] from blood smears taken every four hours for five to seven days during the course of infection have revealed a clear-cut 24-hr. periodicity.

The morphology of the parasite resembles closely the description given by Sinton and Mulligan[1]. Besides, band forms similar to those reported by Brug[5] and a few other characteristics have been observed, and are being studied in detail.

To eliminate the co-existence, if any, of any other species, spleens were removed from some monkeys before or after inoculation. This procedure was found useful by Jaswant Singh *et al.*[3] and Jaswant Singh and Ray[6].

Toxicity of Radiostrontium in Monkeys

As a preliminary to a long-term investigation, eight monkeys have been injected with large doses of pure strontium-90 (25 years half-life) in equilibrium with its short-lived decay product yttrium-90. There is a higher toxicity and greater retention than in other species of animals[1]. Results are summarized below:

Injection dose (mC./kgm.)	Survival time (days)			
2·0		13	15	
1·0	21	23	24	25
0·5		35	56	

All the animals apparently died from anæmia; the hæmoglobin, red-blood cell count and packed-cell volume fall in a remarkably consistent manner; the white-cell count always falls before the red-cell count.

The amount of radiostrontium retained in the body at death was estimated from autopsy radioactivity analysis and from the total activity excreted before death. The retention varied between 90 and 66 per cent. The relative rate of excretion is higher for animals receiving a lower dose. The logarithm of the strontium-90 activity of the daily excreta plotted against the logarithm of the number of days after injection gives a straight line[1] of small slope, with slightly more activity in fæces than in urine. Fresh specimens were assayed for strontium-90 and for yttrium-90 and the relative amount of yttrium excreted was found to be greater for specimens taken a long time after the injection. Details of diet and full hæmatological, histological and radioactivity reports will be published later.

Our thanks are due to Profs. E. E. Edwards and H. E. Huntley and Mr. A. H. Booth, of this College, for their encouragement, and to Dr. J. F. Loutit, Dr. R. M. Mole and the Medical Research Council for their advice and financial support.

Discovery of Iron in Tunicin-forming Blood Cells of an Ascidian

HENZE[1] was the first to show that vanadium is present in the blood of certain ascidians. Webb[2] demonstrated that the metal is accumulated by the primitive families but not by the more specialized families of the Ascidiacea. Also he showed that the vanadium chromogen is located in a special type of cell which he termed a vanadocyte.

Pyura stolonifera (Heller), a member of the relatively specialized family Pyuridæ, is a common zoning animal found on the rocky shores of New South Wales and southern Queensland[3]. Blood was taken from the large vessels in the tests of these animals. Morula-shaped corpuscles, fundamentally similar in appearance to the green vanadium-containing cells of the family Ascidiidæ, comprised between 70 and 75 per cent of the total number of corpuscles. Both spectrographic examination of the ashed blood and colorimetric analysis using phosphotungstic acid gave negative results for vanadium.

The blood was then tested for other metals and it was discovered that organically bound iron was present. This was in the ferrous condition and, as evidenced by histochemical staining, was confined to the morula-shaped corpuscles. Blood from twenty individuals was pooled and centrifuged. The concentration of iron in aliquots of the pooled blood corpuscles was estimated colorimetrically using *o*-phenanthroline. The iron content of the corpuscles averaged approximately 0·5 mgm. per cent of their dry weight. Further, it was established that there was much individual variation in the iron content of the blood, which was correlated with variation in the corpuscle count from individual to individual.

The blood did not exhibit absorption bands in the visible region of the spectrum at room temperature. Additional observations suggest that the iron chromogen did not have a respiratory significance.

When the corpuscles were cytolysed in distilled water, an orange-coloured suspension was obtained and this contained the iron compound. This was non-dialysable and resembled the vanadium chromogen of other tunicates in its strongly reducing properties.

It would appear that in *Pyura stolonifera* an iron compound is present in high concentration in certain blood corpuscles, and that it may be physiologically equivalent to the vanadium chromogen occurring in primitive tunicates.

Additional work upon the species is proceeding, especially with reference to tunicin formation. In subsequent publications the synthesis of tunicin from the cytolysing contents of the morula-shaped cells will be described.

Folin-Wu Prepared Blood-Group Specific Substance *A*

A SIMPLE method for the preparation of blood-group specific substance *A* from Difco's neopeptone by means of the *Folin-Wu* technique of preparing a protein-free filtrate was recently reported[1]. Preliminary chemical, as well as inhibition of isoagglutination, studies were made of products prepared from both hog pepsin and neopeptone[2].

A detailed study has been made[3] of the products prepared from the above substances, with particular attention to the chemical, electrophoretic and paper chromatographic properties.

Total nitrogen (micro-Kjeldahl) and carbohydrate (orcinol method) for products prepared from both pepsin and neopeptone indicate a great deal of agreement in the carbohydrate values—8·2 per cent for the former and 8·7 per cent for the latter. The total nitrogen for pepsin (8·7 per cent) was much higher than in the case of neopeptone (4·8 per cent).

The electrophoretic studies showed considerable variation in the mobilities, and no more could be deduced except that a major and minor component existed. There was no indication of isoelectric points.

Two-dimensional paper chromatography showed fifteen ninhydrin-positive areas. There were variations depending upon the source material. The blood-group specific substance prepared from pepsin appeared to have histidine instead of the hydroxyproline of the neopeptone product. Methionine appeared only in the pepsin product. Galactose, fucose, rhamnose and glucosamine were detected in both products with one-dimensional chromatography.

Purification of Secretin by Freezing Out of Impurities from Methanolic Solution at –80° C.

We recently described a method for the purification of secretin, based on the repeated isoelectric precipitation of impurities from solutions of crude secretin in methanol[1]. The final, lyophilized product had an activity varying, in different preparations, from 600 to 900 cat units[1] per mgm. ash-free substance.

We have found that a further twofold increase in activity may be achieved by dissolving the purified substance to a 1 per cent solution in absolute methanol, adjusting the *p*H to 7·0 and allowing to stand at – 80° C. for a couple of days. An ash-free fraction, comprising about nine-tenths of the protein matter originally present in solution, and including about seven-tenths of the secretin activity, is precipitated. After removal of this precipitate, the purified product is precipitated from the solution with several volumes of water-free ethyl ether.

The product comprises about one-tenth of the protein matter originally in solution, and contains from two- to three-tenths of the secretin activity, as well as practically all the ash. Its activity is about 1,500 cat units per mgm. ash-free substance.

In a few cases we have removed the ash by means of the ion-exchange resins 'Dowex 50' and 'Dowex 2' before dissolving the secretin in absolute methanol. In one case this led to a final product with the activity expected for an ash-free preparation, that is, 1,500 units per mgm. In the remaining cases, however, a considerable loss in activity occurred during treatment of the secretin with the resins.

A Micro Lipid Extractor

In the course of studies of the phospho-compounds of bacteria, an apparatus was designed to make possible the quantitative extraction of phospholipid by the method of Reichert[1] on a micro scale. I have been prompted to give a brief description of this apparatus by other research workers in this laboratory who have found it useful[2].

The method of Reichert consists in heating the material to be extracted with methanol, evaporating to dryness and extracting the lipid with dry ether in a Soxhlet apparatus. The lower limit to the amount of material which can be handled by this method is set by the losses which accompany the transfer to and from the extraction thimble. The amount which could be handled was reduced to a level determined by the gravimetric error by eliminating the necessity for transfer. Both the preliminary treatment with methanol and the ether extraction were carried out in *B* 14 'Quickfit' tubes into which samples were initially weighed. The diagram shows the method of ether extraction, the rate of flow of ether being regulated at about 2 ml. per minute.

The determinations of total lipid contents of a large number of bacteria and bacterial fractions[3] have been found to be reproducible to within the limit of the gravimetric error using 5–50 mgm. of material containing 0·3–5 mgm. of lipid and weighing with an air-damped aperiodic balance reading to 10 μgm.

Toxicity Studies on Silicone Rubber and Other Substances

Tissues which are grown in a culture medium or perfused must not be brought into contact, directly or indirectly, with material which is toxic, and it is preferable if apparatus in use can be sterilized by dry heat. Vulcanized rubber tubing, lubricant greases, and paraffin-lined tubes which are at present used in this work have disadvantages.

Vulcanized rubber tubing is toxic because of its content of sulphur and talc. It requires special treatment before use, does not withstand the usual temperature of a dry heat oven, and must therefore be sterilized by some other means. Lubricant greases which might be used have too low a melting point for sterilization *in situ* on a ground-glass joint. Paraffin-lined tubes are satisfactory for storing plasma but require constant recoating as they can only be used once.

It was thought that by replacing the above with silicone compounds there would be a considerable reduction in the amount of routine laboratory work. These compounds are relatively inert, chemically and physically, and if, in addition, they could be proved to be non-toxic, this would ensure an advance in technique. Silicone rubber, obtainable in the form of tubing, is flexible and unaffected by repeated baking in a dry heat oven. Silicone greases remain viscid over a wide range of temperature, including 160° C. Silicone-lined tubes withstand dry heat and are relatively durable, not requiring to be recoated each time they are in use.

The toxicity of these substances and of fluids stored in silicone-lined tubes towards cells maintained *in vitro* was tested. The cells used included fibroblasts derived from the heart, nerve cells from the spinal cord, epithelial cells from the intestine, and cells from the spleen, all obtained from chick embryos. A total of seven hundred explants, including control cultures, was studied by the hanging drop method. Control and experimental cultures showed a close similarity in respect of rate of growth, contractility of muscular elements, cytological appearance and mitotic activity as determined by counts. These silicone compounds would appear, therefore, to be of value in tissue culture work.

As these materials are available in different grades, the sources of the varieties used in the tests are given below. Silicone rubber: *DSR* 210 (Dunlop Rubber Co., Ltd.) or 181 (Midland Silicones, Ltd.); silicone greases: stopcock and high vacuum (Dow Corning); silicone fluid: *M* 440 (Imperial Chemical Industries, Ltd.) for coating glass tubes to render them water-repellent. Preliminary tests on eleven other grades of silicone rubber with differing physical properties, such as elasticity, suggest that some of these may also prove to be non-toxic. The reaction of the tissues of the intact animal to some of them is now under investigation.

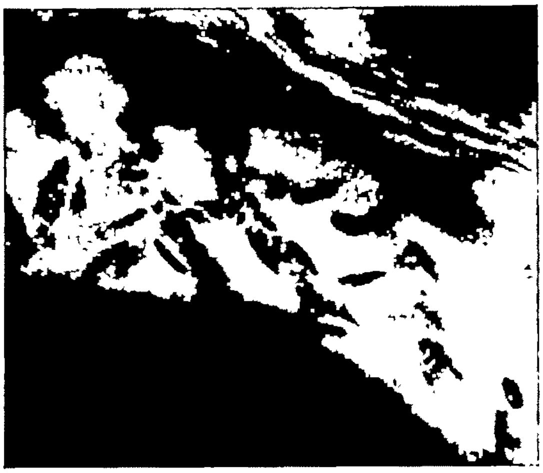
Use of Cyanol in the Study of Blood-vessels in Sheep Skin

As one approach to the problem of the nourishment of the growing wool fibre in its follicle, a detailed study of the distribution of blood-vessels in the skin of sheep and the blood supply to the wool follicle has been commenced in these laboratories.

Because injection techniques are obviously unsuitable for adult animals, a staining method was sought. Various stains for hæmoglobin have been used to visualize blood-vessels in histological sections (for example, that of Pickworth[1]), but these have usually involved long and laborious procedures. The simple and rapid method of Dunn[2], which stains hæmoglobin blue, nuclei red and cytoplasm pink, has not to my knowledge been used previously for this purpose. A slightly modified form of Dunn's method is being used, with good results, on thick sections, and it is thought that this might be of interest to other histologists. Whole-mount preparations have also been made by staining small pieces of skin in cyanol alone.

Dunn recommends fixation in 4 per cent formaldehyde solution buffered to *p*H 7·0. Although buffered fixative was not used here, the formalin was neutralized with sodium carbonate before the fixative (formol-saline) was prepared. It was found, however, that some specimens fixed in formol-saline which had not been neutralized in this way stained satisfactorily. According to the usual practice in this laboratory, the material was not taken below 70 per cent alcohol, after fixation in 5 per cent formol-saline.



Photomicrograph showing part of the capillary network around a wool follicle (dark area to the left). The light area around the capillaries is an artefact caused by the shrinkage, away from the follicle, of the connective tissue at the right. × 680

Although Dunn states that the method is useful for wax sections, better staining was obtained with frozen sections, which show less shrinkage and are also quicker to prepare. Immediately after cutting at 100 microns on the freezing microtome, the sections are placed in 70 per cent alcohol, then stained in cyanol for up to five minutes and rinsed in 70 per cent alcohol (which removes cyanol from regions other than the red blood corpuscles). After this they are counter-stained with safranin for at least five minutes. The latter stain is differentiated in 70 per cent alcohol, and the sections are dehydrated in absolute alcohol, cleared in methyl benzoate and mounted in 'Distrene'.

These thick sections are excellent for demonstrating the distribution of blood-vessels and the general structure and arrangement of wool follicles and their accessory structures in the skin. Although the cyanol only shows blood-vessels when they are full of blood, this disadvantage is overcome because the safranin stains their walls, thus making them visible when empty.

Cellular detail of the vessel walls in the dermal connective tissue (the fibres of which are unstained) is very clear considering the thickness of the sections; different kinds of vessels (for example, arteries and veins) can be distinguished by the differences in structure of their walls. Cellular detail can also be seen in the glands; these finer details are, however, less easily seen in the thicker follicles, which are, of course, stained more densely.

Owing to their clarity, these preparations also show well melanin-containing cells. These pigment cells have been observed in the dermis of sheep skin and around blood-vessels as well as in the epidermis, around sebaceous glands, and in the outer root sheaths of follicles.

My thanks are due to Mr. H. M. Appleyard and Miss M. E. A. Perkin for preparing the photomicrograph.

Preparation of Dry Clay-Gels by Freeze-drying

IN a recent discussion on clay–water relationships[1], it was reported that Prof. U. Hofmann had prepared dry clay-gels by a freeze-drying technique. I have also made a number of samples of montmorillonite in 20–30 gm. batches by a similar method. A 20 per cent aqueous dispersion of the clay, after purification and saturation with the required base, was frozen so as to form a layer about 5 mm. thick over the inner surface of a 2-litre bolt-head flask, which was then rapidly evacuated to a pressure of less than 1 mm. mercury, the evaporated water being trapped by calcium chloride towers. The final product was a curved sheet of pith-like material of fibrous structure which tended to fracture normally to the surface and had properties similar to those of Prof. Hofmann's product. The bulk density was 0·12 gm. per c.c. as compared with a density of 0·82 for the original powdered bentonite. Attempts to prepare similar gels of kaolin and a soil clay fraction failed since the dry products fell to a fine powder.

Nitrogen areas of calcium, sodium and hydrogen montmorillonite obtained by the standard Brunauer–Emmett–Teller method were 70, 49 and 58 m.^{2} per gm. respectively. The area of the calcium-saturated clay was the same as that of the original powder. During the preliminary degassing, which was carried out at 10^{-4} mm. mercury for 100 hr., the gels became considerably lighter in colour and gradually lost their structure, tending to fall to a fine powder. A similar loss of structure has been observed during long heating at 110° C. and after storage over phosphorus pentoxide. These observations suggest that the clay crystals are held in a micelle by hydrogen bonding with water molecules.

Curves representing the swelling at different relative humidities were obtained by measuring the elongation of pellets of compressed clay exposed in desiccators. The curve for calcium montmorillonite has two plateaux, and indicates that swelling takes place in two clearly defined stages corresponding to expansion of the lattice from 9 A. to 12 A. and from 12 A. to 15 A. The curves for hydrogen and sodium montmorillonite each exhibit only one plateau, and swelling seems continuous at higher humidities. No swelling was observed with kaolin or soil clay fractions. These results in general are in agreement with those obtained by Hendricks, Nelson and Alexander[2] using X-ray analysis.

The Serpentine Minerals

SELFRIDGE[1] has shown that the serpentine minerals can be divided by the evidence of their X-ray powder patterns into two main groups, chrysotilic and antigoritic. Five distinct varieties from each group which show varying degrees of fibrous or splintery texture have been examined in this department, using oscillation photographs to determine in each case which crystallographic direction lies parallel to the fibre axis.

The chrysotilic specimens, including schweizerite, marmolite and chrysotile asbestos itself, all have a repeat distance of 5·3 A. parallel to the fibre axis, whereas in the antigoritic varieties, including picrolite, picrosmine and antigorite (Hokitika), the repeat distance along the fibre axis was found to lie between 9·2 and 9·3 A. Furthermore, antigorite from Mikonnui, New Zealand, was described by Aruja[2] as having a fibrous texture parallel to the *b* axis, and platey single crystals of this variety have a marked {100} cleavage in addition to the expected {001} cleavage.

The basic structure of these minerals is assumed to be that of a magnesium analogue of kaolinite (having cell dimensions approximately $a = 5{\cdot}3$ A., $b = 9{\cdot}2$ A., $c = 14{\cdot}6$ A., $\beta = 91°–93°$), and the fibrous nature of chrysotile asbestos is attributed to cylindrical curvature of the sheet units about the *a* axis, in some cases forming hollow tubes[3]. The results presented here would suggest that in the fibrous antigoritic varieties curvature has taken place about the 9·2-A. axis.

It is also of interest that several workers have noted in fibre photographs of chrysotile very weak subsidiary layer lines which correspond to a repeat distance of 9·2 A.[4].

Suggestions have been made that platey antigorite differs from chrysotile in certain chemical features, for example, replacement of magnesium by aluminium, or a low (Mg, Al) : (Si, Al) ratio, which allow the tetrahedral and octahedral layers of a sheet to fit together without bending. In view of the structural distinction outlined above, it seems likely that, with a given chemical composition, two types of serpentine mineral may exist, one chrysotilic and one antigoritic, with [100] or [010] as fibre axis respectively. Which type occurs in a given instance may depend upon the physical conditions prevalent at the time of crystal growth, for example, anisotropic pressure and orientation of parent material. With increasing radius of curvature these two types may converge to give a platey non-fibrous variety such as the one from Caracas, Venezuela[5].

Finally, it is worth mentioning that the possibility of curvature about the *b* axis favours an explanation of the multiple *a* axis of antigorite (Mikonnui) along lines similar to those suggested by Onsager[6].

Further investigation, by X-ray and chemical methods, of this and related problems is in progress in this Department. I am grateful to Prof. W. A. Deer and to Dr. G. D. Nicholls for helpful advice and discussion.

Recombination without Sexual Reproduction in *Penicillium chrysogenum*

THE technique devised by Pontecorvo and Roper[1,2] for genetic analysis outside the sexual cycle in filamentous fungi and applied to the imperfect fungus *Aspergillus niger*[3,4] has now been successfully adapted by us to another imperfect fungus, *Penicillium chrysogenum*, the species used for penicillin production.

Starting from strains ultimately tracing back to Q176 *Wis.*, which has green conidia and no growth-factor requirements ('prototroph'), strains with yellow or white conidia, with one or two different growth-factor requirements ('auxotrophs'), and with normal or stunted ('dwarf') growth were obtained by various ultra-violet irradiation steps. The strains used were: 22*y* *dw*-1, yellow conidia, requiring hypoxanthine, 'dwarf'; 7*w* *dw*-4, white conidia, requiring cystine, 'dwarf'; 22*y* 13, yellow conidia, requiring hypoxanthine and methionine, normal growth; 7*w* 16, white conidia, requiring adenine and cystine, normal growth.

'Balanced' heterokaryons were synthesized by mixed inoculation of 22*y* *dw*-1 + 7*w* *dw*-4, and of 22*y* 13 + 7*w* 16. The heterokaryons were not as easily obtained in this species as in the two previously used, due mainly to its extremely slow growth and great 'staling' reaction. As expected, the heterokaryons differed from the component strains in being 'prototrophs', that is, able to grow on unsupplemented Czapek–Dox medium ('minimal medium') and, in the case of the first combination, in having normal, not stunted, growth habit. These heterokaryons were kept by transfers of hyphal tips on minimal medium. They produced a mixture of yellow and white conidia, turning greenish with age, a situation more like that of heterokaryons in *Aspergillus nidulans*[5] than that in *Aspergillus niger*[4]. The overwhelming majority of the conidia from the heterokaryons gave origin to colonies of either one or the other component types.

Plating on minimal medium of conidia from the heterokaryons at densities of 10^6/dish gave from 0·3 to 4 green-spored colonies per 10^7 plated conidia. Furthermore, about 1 in 100 of the few heterokaryotic colonies arising anew from these platings gave a green sector. Isolation of the green colonies, and of the green sectors from the heterokaryotic colonies, followed by purification by single conidium micromanipulation, led to the establishment of heterozygous diploid strains.

That these green-spored strains were actually diploid and heterozygous was shown by: (1) their 'wild type' phenotypes, that is, green conidia, normal morphology and prototrophy; (2) the fact that the majority of single conidia bred true, differently from the single conidia of heterokaryons which gave origin to colonies of either one or the other parental types; (3) the diameter of their conidia, larger than the wild type or the heterokaryons; (4) segregation and recombination as presently described.

After purification, by single conidium isolation, of diploid $\frac{22y\ dw\text{-}1}{7w\ dw\text{-}4}$, its conidia were plated on fully supplemented medium. 1,010 colonies from this plating were isolated and classified as to colour, morphology and requirements with the following results.

Green, adenine-requiring, normal morphology	1
Yellow prototroph, normal morphology	2
Yellow prototroph, dwarf	2
Yellow, adenine-requiring, dwarf	1
White prototroph, normal morphology	12
White prototroph, dwarf	6
Green prototroph, normal morphology	964
Green prototroph, dwarf	5
Non-sporing, prototroph, normal morphology	17
Total	1,010

A proportion of the 1,010 colonies showed sectors, some yellow, some white, and some non-sporulating or with growth habit different from that of the mother colony. Isolation from 21 of these sectors, each from a different colony, and further tests gave: 14 white and 5 yellow prototrophs, with normal morphology; 1 yellow prototroph, dwarf; and 1 green, cystine-requiring, with normal morphology. Isolation of yellow and white sectors from the green adenine-requiring strain mentioned in the list above gave adenine-requiring strains, yellow and white respectively. Thus eleven new different phenotypes (out of a possible minimum of twenty-one) have already been obtained.

A similar analysis of diploid $\frac{22y\ 13}{7w\ 16}$ gave analogous results.

This work, preliminary as it is, is sufficient to show that heterozygous diploid strains can be synthesized in *P. chrysogenum* by means of Roper's[6] technique, and that these diploids give origin to strains associating and recombining the properties of the starting strains.

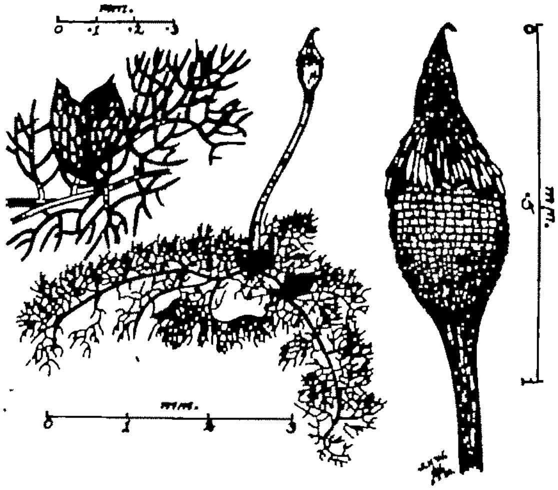
Nemataceæ, a Moss Family New to Australia

The Nemataceæ embraces only two known species, namely, *Ephemeropsis tjibodensis* Goebel em. Fleischer, which is epiphyllous, ranging from Siam through the Indonesian Islands to New Guinea, and *E. trentepohlioides* (Renner[1]) Sainsbury[2]—until now believed endemic in New Zealand, where it is scattered through both islands, occurring on bark and twigs (of *Rubus*, *Leptospermum*, *Fuchsia* and *Coprosma* spp.). Both mosses are small and inconspicuous, with very remarkable gametophytes consisting almost entirely of matted, freely branched protonemal filaments which creep over the substrate. Normal foliage is represented by a single series of three or four minute nerveless leaves at the base of each female inflorescence (or seta, which may be several millimetres long). The differences between these species are fully discussed by O. Renner[1] and G. O. K. Sainsbury[2], and it seemed likely that one or other would eventually be found in eastern Australia.

On December 13, 1952, while examining mosses in virgin beech forest along the Florentine Valley west of Mt. Field National Park, Tasmania, I collected some dead beech twigs (*Nothofagus cunninghamii*) bearing festoons of epiphytic musci, including *Weymouthia mollis*. Later, in the herbarium, a minute unfamiliar capsule (with calyptra attached) was detected on one branchlet. It proved to be that of an *Ephemeropsis*; but most careful searching over all the other *Nothofagus* twigs failed to disclose a second capsule, or even another plant, of this intriguing moss. So, short of destroying the solitary sporophyte, it was impossible to study either peristome or spore details. Mr. Sainsbury (of Wairoa,



Ephemeropsis trentepohlioides (Renner) Sainsbury, 1951, drawn from a Tasmanian specimen

N.Z.) has kindly examined my Tasmanian collection and pronounces it identical in vegetative characters with the New Zealand *E. trentepohlioides*; he believes that an important extension in the known range of that species has now been established. The discovery of additional Australian material on beech, and probably other rain forest trees or shrubs, is much to be desired.

Relation of Witchweed (*Striga*) to Fertility in Tropical Soils

MUCH is written upon the subject of soil exhaustion in Africa, and it seems to be generally accepted that the soils of the tropics require careful management, including frequent periods of rest, if fertility is to be maintained. In the great clay plains of the Sudan[1] in particular, it has been emphatically stated that uncontrolled continuous cultivation of land around water points and villages is responsible for the poor crops and general poverty of the villagers, and that only the provision of new villages at new water points, where cultivation can be rigidly controlled, can solve the problem. It cannot be doubted that soil erosion is responsible for reduction of yields in some cases. The question then arises, what is the reason for the very markedly poor yields of the grain and fodder crop, *Sorghum vulgare*, Pers., on the village cultivations, where soil erosion is not marked? The answer in the northern and central Sudan seems to be the root parasite *Striga hermontheca*, Benth., which is prevalent in more or less degree wherever this crop is grown, being indigenous as a parasite of the native grasses. By suitable treatment with hormone weed-killers[2] it has been shown that it is possible to kill much of the *Striga* and bring about very considerable increases in yield on irrigated land. During the 1952 season, an experiment was carried out on a piece of village land near Gedaref, in the eastern Sudan, which has been under cultivation for longer than can be remembered by the oldest inhabitants. The result was that sorghum on the untreated plots yielded 427 lb. of heads to the acre, whereas that on plots treated against *Striga* yielded 1,183 lb. of heads to the acre (*P* better than 5 per cent). This latter would be a fairly good yield for newly opened land.

It is interesting to note that one of the criticisms which has been levelled against the practice of this treatment for *Striga* control is that it will make possible cultivation without rotation on village lands. If, however, as here, the removal of *Striga* is capable of raising the yield on so-called 'worn-out' lands to a level comparable with yields obtainable from newly opened land, the reply might be made by asking whether the land is worn out, or merely over-parasitized? Only further experimentation will show whether, as a recent summary[3] states, *Striga* is only serious on worn-out soils, or whether, as I suggest, the 'wearing-out' is due to *Striga*, on these lands of marginal rainfall.

An Effect of Parasitism on *Balanus balanus* (L.) da Costa

THE parasitism of barnacles of many species by various isopods, gregarines and trematodes, often with the resultant castration of the host, is well known. Recent observations on *Balanus balanus* collected in the Firth of Clyde, at a depth of about 20 metres, have shown that parasitism may not result in complete castration, but only in non-liberation of the nauplii.

This barnacle spawns during the spring: a collection was made when the main spawning period was known to have ended, and several hundred individuals of all size-groups examined for the state of the ovaries. Only a single individual was found with embryos, the remainder being either immature or spent. Further examination showed this individual to be heavily parasitized by a protozoan, and although not specifically identified it seems probable that it was a gregarine, these being known to be of common occurrence in other *Balanus* species[1].

On teasing out into sea water, the liberated stage I nauplii appeared to be quite normal, swimming vigorously. However, within a few minutes almost all the nauplii (stage I) had moulted to give normal stage II nauplii.

It would seem, therefore, that the presence of the parasite, while not effecting castration, had prevented normal release of the nauplii, and that development of the latter had continued to some extent within the mantle cavity, so that on release extremely rapid moulting to stage II took place.

FORTHCOMING EVENTS

(*Meeting marked with an asterisk * is open to the public*)

Tuesday, July 21

ROYAL ASTRONOMICAL SOCIETY, in co-operation with King's College, Newcastle upon Tyne (University of Durham), and the Newcastle upon Tyne Astronomical Society (at the Newcastle upon Tyne Royal Grammar School, Eskdale Terrace), at 8.15 p.m.—Prof. W. M. Smart: "The Origin of the Earth".*

Wednesday, July 22

ROYAL ASTRONOMICAL SOCIETY, in co-operation with King's College, Newcastle upon Tyne (University of Durham) (in the Stephenson Building, King's College), at 4.30 p.m.—Scientific Papers.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DEMONSTRATORS (with engineering degree or equivalent, and preferably with industrial experience) IN MECHANICAL ENGINEERING, to assist in organization, preparation, and control of work to final B.Sc.(Eng.) standard in materials, metallurgy, meteorology, heat engines and aerodynamics laboratories—The Principal, Royal Aircraft Establishment Technical College, Farnborough, Hants (July 25).

LECTURER (Grade III or Grade II) IN THE DEPARTMENT OF ORGANIC CHEMISTRY—The Registrar, The University, Bristol 8 (July 25).

ASSISTANT EXPERIMENTAL OFFICER (with general certificate of education (advanced level) or pass degree in biological subjects, and preferably with experience in biochemistry and/or genetics) to work in Edinburgh on research into the nutritional requirements of *Drosophila* and the genetic control of these needs—The Secretary, Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1 (July 27).

GAS PLANT MANUFACTURER'S DEVELOPMENT COUNCIL SCHOLARSHIP—The Registrar, The University, Leeds 2 (July 30).

ANALYTICAL CHEMIST, Senior Experimental Officer grade (with degree in chemistry or equivalent qualification and experience in analytical work) to collaborate with plant breeders and grassland agronomists in the routine analysis of plant material used in breeding and research work, and to take charge and responsibility for the establishment of a chemical laboratory—The Secretary, Welsh Plant Breeding Station, Penglais, Aberystwyth (July 31).

ASSISTANT EXPERIMENTAL OFFICER IN THE MARINE LABORATORY, Aberdeen, for investigation of physical conditions in the sea (water movements, currents, temperature, salt content, etc.) in relation to fishery biology, with active participation in the collection of data at sea on a research vessel or fishing vessel—Establishment Officer, Scottish Home Department, Room 264, St. Andrew's House, Edinburgh 1 (July 31).

DEMONSTRATOR IN BOTANY (preferably wanting research experience in cytology or plant biophysics)—The Registrar, The University, Leeds, 2 (July 31).

LECTURER IN BOTANY, and a DEMONSTRATOR IN BOTANY—The Registrar, The University, Leeds 2 (July 31).

RESEARCH ASSISTANT IN THEORETICAL PHYSICS—The Registrar, King's College, Newcastle-upon-Tyne (July 31).

ASSISTANT LECTURER IN AGRICULTURAL CHEMISTRY (with special qualifications in animal nutrition), and a DEMONSTRATOR IN AGRICULTURAL CHEMISTRY—The Registrar, The University, Nottingham (August 1).

ASSISTANT LECTURER IN AGRICULTURE—The Registrar, The University, Reading (August 1).

ASSISTANT LECTURER IN PETROLOGY—The Registrar, The University, Nottingham (August 1).

MATHEMATICIANS (Scientific Officer Class, with first- or second-class honours degree in mathematics or equivalent, and Experimental Officer Class, with H S.C. (Science) or equivalent) in Ministry of Supply Research and Development Establishments at Farnborough, Amesbury and Malvern, for work in aerodynamics, aircraft structures, ballistics, radio or radar, high-speed electronic calculating machines—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.117/53A. (August 1).

DEMONSTRATOR (with honours degree in chemistry or biochemistry) IN THE DEPARTMENT OF CHEMISTRY AND BIOCHEMISTRY—The Dean, St. Thomas's Hospital Medical School, London, S.E.1 (August 4).

PHYSICISTS (with good honours degree or equivalent) IN THE PHYSICS DEPARTMENT of the Central Research Establishment, Stoke Orchard, Cheltenham, Glos, for fundamental and other studies in connexion with technical processes of coal preparation and treatment—The National Coal Board, Central Research Establishment, Cheltenham, Glos, quoting TT/652 (August 5).

SUPERINTENDENT (Deputy Chief Scientific Officer) (with first- or second-class honours degree in a science subject or equivalent qualification) in the D.S.I.R. Metrology Division, National Physical Laboratory, Teddington—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting 84228/53 (August 6).

LECTURER IN BIOCHEMISTRY (preferably with special experience in biochemistry of micro-organisms)—The Secretary, The University, Aberdeen (August 7).

PLANT BREEDER (Fruit) (Scientific Officer grade or Senior Scientific Officer grade) in the University of Bristol Research Station, Long Ashton, Bristol—The Registrar and Secretary, The University, Bristol 8 (August 8).

SENIOR BIOCHEMIST IN THE DIVISION OF PLANT INDUSTRY, Commonwealth Scientific and Industrial Research Organization, Canberra, for investigations into carbohydrate and protein metabolism, the role of micronutrients, the action of growth substances and the biochemistry of cell differentiation, with opportunity for further research development in which collaboration with workers in the fields of plant genetics, physiology and microbiology may be a special feature—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting 130/189 (August 29).

LECTURER, Grade I or Grade II (with university degree with physics a major subject) IN PHYSICS, at the University of Queensland—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 31).

LECTURER IN GEOLOGY (with special qualifications and experience in mineralogy and petrology, or in palæontology, or in stratigraphy)—The Registrar, University College, Keele, Staffordshire (August 31).

SCHOLARSHIPS IN DEMOGRAPHY, GEOGRAPHY and STATISTICS, including mathematical statistics, in the Australian National University, Canberra—The Secretary, The Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (Canberra, August 31).

LECTURER or ASSISTANT LECTURER IN PHYSIOLOGY in the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (September 10).

ASSISTANT LECTURER AND DEMONSTRATOR IN PHYSICS, and an ASSISTANT LECTURER AND DEMONSTRATOR IN PHYSIOLOGY—The Secretary, Queen Elizabeth College, Campden Hill Road, London, W.8.

ENGINEERS AND PHYSICISTS (Senior Scientific Officer and Scientific Officer grades (Ref. A.246/52A), and Experimental Officer and Assistant Experimental Officer grades (Ref. A.247/52A)), in the Royal Naval Scientific Service Experimental Establishments in the London, Portsmouth and Weymouth areas and Scotland—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting appropriate Ref. No.

LECTURER (with honours degree, preferably with special qualification in electronics, electron microscopy, photoelasticity or other branch of applied physics) IN PHYSICS—The Secretary, Royal Technical College, Glasgow.

LECTURER (Grade B) IN ELECTRICAL ENGINEERING—The Clerk of the Governing Body, Battersea Polytechnic, London, S.W.11.

ORGANIC CHEMIST (Ph.D.) IN THE CHEMICAL RESEARCH LABORATORY, to work with a team in the steroid field—W. Stansfield, "Lyndhurst", Nether Edge Hospital, Sheffield 11.

PHYSICAL CHEMIST (Ph D.)—The Secretary, British Rayon Research Association, Barton Dock Road, Urmston, Manchester.

SCIENTIFIC OFFICER, male (B.Sc. with first- or second-class honours, or equivalent qualifications, with chemistry as the principal subject) in the Mineral Resources Division of the Colonial Geological Surveys, London, S.W.7, to undertake chemical analysis of rocks and minerals for scientific and industrial purposes, and in particular laboratory investigation of clays, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting F318/53A

Industrial Plant in use overseas

"Quickfit" All-glass Industrial Equipment

brings laboratory conditions of cleanliness and visibility to the help of manufacturing production. Pipe lines, heat exchangers, fractionating columns, batch stills, evaporators and condensers are all made in glass. They are light in weight, mechanically strong, compact and robust. Glass brings a new and higher standard of production to chemical, foodstuff and drug manufacture. It is an assurance of quality, purity and simplicity of control. Get into touch with us.

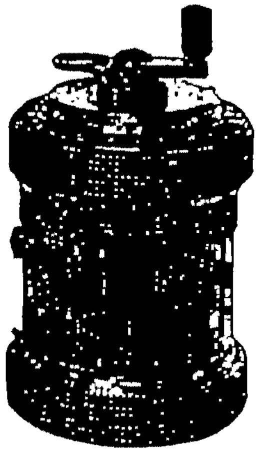
CURTA

THE IDEAL CALCULATING MACHINE
for
SCIENTISTS
and
RESEARCH WORKERS



CURTA Model II

Please write or telephone for a demonstration

Easy, speedy, and silent operation. Tens transmission and visible dials throughout.

Highest quality precision construction.

Model I. Capacity 8×6×11 Weight 8 oz.
Model II. Capacity 11×8×15 Weight 12 oz.

It will be seen that both models are readily portable.

The Model II Curta, now available, has 15 figures in the Product Register and is a specially useful machine for all statistical calculations, such as summing squares, Mean Deviations, etc.

THE PURPOSE OF A UNIVERSITY

THE proceedings of the Congress of Universities of the Commonwealth which was held in Cambridge last week were divided into a number of sessions on specific topics. Nevertheless, permeating the whole, there was the thought of the purpose of university education. Some recent pronouncements on this topic are thus of immediate interest.

At the recent jubilee thanksgiving service of the University of Liverpool, the Archbishop of York, Dr. Cyril Garbett, urged that the noblest task of a university is to encourage in its students the disinterested and relentless search for truth. First and foremost, he said, a university exists for knowledge, and while earnestness in the search for truth is characteristic of what is best in the younger generation, those responsible for the work of a university should manifest a fearless and disinterested love of truth in all its departments. This is the most effective safeguard against the attack upon freedom.

The existence of a sufficient number of men and women who have been taught from their student days to value truth and to question and to criticize unproved assertions is the best defence against this danger, as has been shown in the United States when the academic freedom of the universities was threatened by security proceedings. That may well be the most important social function of the universities at the present time, and it may have determined Dr. J. B. Conant's choice of the title "Education and Liberty" for his recent book on the role of the schools in a modern democracy. Dr. Conant took as his text the words Thomas Jefferson wrote to Washington in 1788: "It is an axiom in my mind that our liberty can never be safe but in the hands of the people themselves, and that, too, of the people with a degree of instruction"; and he discusses principally the changes in education at the school-level which are necessary in the United States to ensure the safety of freedom. Nevertheless, his theme is more related to that of the purpose of a university than would immediately be apparent to those unfamiliar with the overlap of the American college system with secondary education and university education in Great Britain.

Dr. Conant's book is appropriately recalled here because, although he says little directly about the search for truth or the defence of freedom, he is concerned above all with making men and women competent to play their full part in the world to-day. This, said Dr. Garbett, is the second function of the university; and here, too, in the development of personality in its students, in encouraging the exercise of responsibility and initiative, which, if a democracy is to endure, must be possessed and used by the many and not by the few, the university exercises a social function. Sir John Stopford, speaking later on the same day, emphasized the civic as well as the national and regional functions of the universities; and in referring recently to the work of the University Appointments Board at Manchester, suggested that the actual placing of graduates might well be less valuable than advisory work, in which the Board helped them to choose the appropriate discipline.

That point was elaborated further by Sir Hector Hetherington, vice-chancellor of the University of Glasgow, in his Essex Hall Lecture, "The Social Function of the University", recently published*. It was also put, but somewhat differently, by Lord Beveridge in writing on the main purpose of university life, as learning to use freedom. The extent to which a university succeeds in this largely determines that to which its graduates will succeed in taking their proper place in industry and in the public services, as well as in scholarship and the learned professions, and in breaking down inhibitions against their employment.

Sir Hector Hetherington lays his main stress on education as the prime social function of a university. He recognizes, too, that there is also the communication of a culture and the discovery of new knowledge or research. Of the last, he observes that because real research or real scholarship is hard and punishing work, there is danger that the balance of interest of the ablest people may tilt too heavily in that direction. A university cannot be built if too many of its leading people come to regard teaching as second best. Also, the difference between research in the arts and in the sciences has been responsible for a change in the climate of opinion, and art disciplines, he thought, in changing their direction have moved onesidedly and a little lost their way. Also, while research is a superb and fortifying discipline, there is a tendency, he said, for it to be undertaken, both in the arts as well as in the sciences, before the student has obtained the indispensable comprehensive grasp of the material of his subject.

Sir Hector Hetherington's conception of the university's function of education is not narrow. It embraces the content as well as the communication of knowledge, the ways and habit of winning knowledge, and the judgments to be made in its assessment and use. To this he devotes the major part of his lecture, and it will be noted that, by and large, he confirms here much of what was said by Sir Richard Southwell in his Trueman Wood Lecture before the Royal Society of Arts on May 13. Sir Richard Southwell was dealing specifically with training in science and technology, and insisted that the structure of technological education in any country is, and should be, conditioned by the structure of its industry, and that this in turn is conditioned by its history. For this reason he was averse to rapid change, quoting Bacon's warning that "it were good . . . that men in their innovations would follow the example of Time itself". Sir Richard was opposed both to the lengthening of university courses and to the proposal to build a technological university on the lines of the Delft or Zurich Technical Colleges or the Massachusetts Institute of Technology. He did not deny the need for training to a high level in the specialized technologies of industry, but he insisted that the study of the application of science should take place where its development occurs—the vicinity of works or of great research institutions; application cannot be presented *in vacuo*.

Sir Richard was anxious to safeguard the undergraduate against demands which threaten his wider education, and he visualized the universities as concerned primarily with the science which is pursued with the view of application, not directly with applications. At the undergraduate-level, the teaching should endeavour to instil a knowledge of the basic principles and the power to grasp essentials of a problem. At the postgraduate-level, however, the university should not only continue to supervise research but should also provide courses in the newer and harder parts of applicable science, and here he stressed the need for close contact and co-operation between the universities and the monotechnics and industry.

Sir Hector Hetherington reaches similar views from rather a different angle. He seeks first to find the criteria which should determine the contribution of the university to the making of a professional man. Professional competence, he points out, calls for more than can be provided by any university; equally, the highest level of professional service calls for more than technical skill. Accordingly, the university's first contribution is to teach the professional man what he needs to know, and to teach him systematically, organically and thoroughly, so that he is master of it, and can use it to guide his actions in ways yet unforeseen.

As the basis of intelligent participation in the affairs of his society, however, the professional man needs also to see his specialisms in their relationship to one another, as mutually sustaining elements in a living system, the place and claim of which in the larger context of human experience and reflexion he must to some extent understand. Thus, like Sir Richard Southwell, Sir Hector claims that the aim of university teaching should be to provide for all kinds of students, not a professional training but an education for professional service, a discipline which fits a man not only to meet the technical demands of his vocation, but also to share the concerns of a civilized society, to accept the enjoyments, the privileges and the responsibilities of the continuing life of his community.

To meet this demand for wisdom as well as power, Sir Hector suggests first that the universities and their teaching staffs should take quite seriously the precept that their business is education and not training. Accordingly, the universities should accept as falling within their province only those professions the basic disciplinary requirements of which are capable of being the instruments of a genuinely educational process, of recognizable breadth and depth. They should admit all which meet this criterion, but no others. Like Sir Richard Southwell, he holds that if no more is wanted than techniques, it is not a matter for the university, although if genuine and systematic learning is involved, the university should, in principle, be ready to be concerned.

Sir Hector Hetherington does not think that British universities have been at fault in this regard, nor does he think there is general disagreement with his second principle, that universities should accept only those students whose attainments give some assurance of their ability to sustain the discipline of a university education. Controversy has arisen rather over the application of this principle, and he pointed out that university requirements must be conceived not only in terms of what the universities think to be necessary, but also in terms of their effect upon the general working of the schools. Further, the duty lies upon the university system as a whole of seeking to provide places for all who are fit and who desire to enter, though not necessarily the places which the candidates profess a desire to occupy: the universities must try to keep their services in some kind of balance with effective demand.

---

* The Social Function of the University. By Sir Hector Hetherington. (Essex Hall Lecture, 1953.) Pp. 29. (London: Lindsey Press, 1953.) 2s. net.

The third point made by Sir Hector relates to the formulation of university curricula. The primary requirement is that sovereign place at the university should be given to the educational rather than to the professional end. The professional intention prescribes the disciplines through which the educational end is to be achieved; but achievement is only possible if the content of every element in the programme and the mode of its presentation are weighed by an educational rather than by a professional measure. Sir Hector recognizes that this calls for a liberalizing, and a lightening of specialist courses, at the very moment when the growing complexity of professional services invites the further elaboration of specialist courses. None the less, it is inescapable if we accept the proposition that the university's primary objective is an educated man rather than an expert trained to the highest point of the moment's need.

Sir Hector pointed to some of the implications for the social life of the university, particularly the design and building of its organic life so as to provide for more abundant contact between student and staff in small groups and for the vital contact of minds; and in the ordering of courses and the scrutiny of the educational value of subjects admitted to a university curriculum, so that the university might realize its creative power to the full. While he said little on the university's function in the communication of culture, he said enough to bring to light the central issues as clearly as Sir Walter Moberly has done. A university is above all dedicated to the pursuit of truth, and there is no other way to truth than by untrammelled thinking, by following the argument wherever it may lead and by meeting the critical encounter of judgments other than one's own. Nor can an institution long endure if it has at its heart no more than a bundle of negations; and in his review of the social functions of the university, Sir Hector finds grounds for confidence for the future of the university and the society in which it exists, precisely because the conditions attached to its freedom of inquiry and teaching—responsibility and competence—have such a positive and constructive role in the society of to-day. Upon their exercise, as Dr. Garbett pointed out, the future of democracy largely depends; and Sir Hector concluded his lecture on a confident note that by patience and humility the universities would discharge their responsibility and provide society not merely with leadership but also with wisdom and vision.

THE ESSENTIAL OILS INDUSTRY

The Essential Oils

By Dr. Ernest Guenther. Vol. 5; pp. xvii+507; 70s. net. Vol. 6; pp. xvi+481; 73s. 6d. net. (New York: D. Van Nostrand Co., Inc.; London: Macmillan and Co., Ltd., 1952.)

It seems a happy necessity that has finally extended the number of Dr. Ernest Guenther's volumes to six. In this respect, as in its total of well over a million words, the work now matches Gibbon's "Decline and Fall"; and in well-ordered presentment of the fruits of enormous study, it is not unqualified to sustain the comparison. Fittingly, therefore, recalling Gibbon's memorable introspection on the completion of his task, one may congratulate Dr. Guenther on the recovery of his freedom, sympathize with his sober melancholy in taking leave of an old and agreeable companion, and assure him as to the establishment of his fame.

Admittedly, the scientist's achievement is less spectacularly single-handed than the historian's. As noted in the reviews of the earlier volumes[1] and exemplified in Dr. Leo Goldblatt's monograph on the American turpentine industry in Vol. 6, Dr. Guenther has made way for able specialists in particular sections, constituting perhaps one-tenth of the whole. Nor can the scientific world be unmindful of a great debt to the firm of Fritzsche Brothers, without whose unstinted support the publication could evidently not have been a practical possibility. Yet Gibbon's monomachy was a triumph exclusively of the library, while Dr. Guenther has refought his battles on the very ground, in the pleasant fields of Grasse and in regions much more remote: a valuable instance is his first-hand study, in Vol. 5, of the complex fractionation and grading of ylang-ylang oil as practised in the Madagascar islet of Nossi-Bé. Before relinquishing the comparison, let it be said that Dr. Guenther's prose, while rightly refraining from the Roman majesty, is noticeably free from those infelicities to which the merely industrious compiler is so commonly prone.

The two present volumes, continuing from Vols. 3 and 4 their account of individual essential oils, deal chiefly with the products of those plant families which, though low in the scale of quantitative output, gain importance from their commercial history and from their special characters as perfumes and flavours. Here, therefore, are most of the examples of the preparation of concretes and resinoids by non-distillation methods: processes as old as Homer, such as the extraction of rose oil into fatty pomades, or as recent as the extraction with such newer solvents as butane, by which the hitherto unattainable concrete of lily of the valley is now being prepared.

Though the pure chemistry of the constituents of essential oils was formally dealt with in Vol. 2, Dr. Guenther has profited by his opportunity of recording subsequent advances in this field. To quote only a few examples from the present volumes, the monograph on *Thuja plicata* discusses the naturally occurring *cyclo*heptanone derivatives (tropolones) down to the synthesis of the three isomeric thujaplicins in 1951. The account of oil of hops includes a survey of recent investigations on the structure of α-caryophyllene and its identity with humulene. Among other compounds for which these volumes record structural formulæ proposed, revised or confirmed since the publication of Vol. 2 are cedrene, lanceol, β-santalol, zingiberene, kessyl alcohol, luparol and the polyacetylenic compounds of the "matricaria-ester" type. Noteworthy also are the first records of the natural occurrence of a sulphoxide (sulphoraphene, in oil of radish), the tricyclic terpene tricyclene in hemlock-spruce oil, and piperettine, a homologue of piperine, in oleoresin of pepper.

Analytical procedures described in Vol. 1 have also been amended where necessary in view of later work: for example, the thiosulphate factor in ascaridole determination. One might wish, perhaps, for fuller documentation of the statement that the halogen test (for synthetic benzaldehyde as opposed to natural oil of bitter almonds) has lost much of its importance owing to the production of the synthetic material in a higher state of purity. It is not clear whether this opinion takes account of very delicate chlorine determinations by the lamp method[2], to which the book does not explicitly refer.

Consideration of the six volumes as a whole may well prompt the reflexion that the essential oil industry has been singularly blessed in the production of such a book at such a juncture as the present. Even a few years ago, it would have been impossible to include much of the material descriptive of new and rationalized production techniques, which may be considered as prefiguring the industry's future; while in even a few years more, oblivion perhaps may begin to overtake much of its historic and romantic past—the buccaneers and galleons, and such strange contrasts as that between the sandalwood of Mysore, owned and accounted for to the last stick by a solicitous government, and the copaiba of Brazil, produced obscurely out of Amazon jungles by native woodsmen calling no man master. To students of either past or future, the book must be equally invaluable.

In view of the progressive additions of new work, to which reference has already been made, a comprehensive index is a necessity for making the fullest use of the book. This is provided in the sixth volume, and extensive trials of its adequacy indicate it as an ending which may be said to crown even a *maximum opus*.

SCIENTIFIC THOUGHT THROUGH THE MIDDLE AGES

Augustine to Galileo

The History of Science A.D. 400–1650. By A. C. Crombie. Pp. xv+436+12 plates. (London: Falcon Educational Books, 1952.) 42s. net.

"WE have now to consider more especially a long and barren period, which intervened between the scientific activity of ancient Greece, and that of modern Europe; and which we may therefore call the Stationary Period of Science. . . ." The quotation from the "Dunciad" which precedes the above passage indicates the probable source of William Whewell's judgment on the science of the Middle Ages. The almost universal self-complacency of the eighteenth century was expressed with such linguistic facility as to create a mist between later scholars and medieval ideas, which despite the wind of criticism of Duhem, Haskins and many others has been slow to clear. Indeed, even in the recent literature of Great Britain it would not be difficult to find judgments differing little from that of Whewell. Dr. A. C. Crombie's book is therefore doubly welcome; for, providing as it does the first reasonably complete survey of the period within a moderate compass, it will be an invaluable work of reference for the medieval historian and a richly rewarding study for those men of science for whom last year's books are not already out of date.

The plan of the book is based on the sound assumption that to do justice to the history of an epoch we must first make sure that we understand the nature of the questions to which answers were then being sought; for only by so doing can we make sense of the answers—or what the inquirers of far-off days thought were answers. To achieve this task, Dr. Crombie reviews in turn the science of Western Christendom up to the renaissance of the twelfth century; the subsequent reception of Græco-Arabic science; and the flowering of scientific thought born of this fertilizing influence. Stepping back from the stream of history, he surveys the relations of science and 'technics' throughout the whole medieval period, and concludes his review of that period by a careful study of the gradual undermining of the Aristotelian authoritarianism (in this sense, as Whitehead reminded us, Aristotle was not an Aristotelian) within the medieval period itself. The last section of the book—running to well over a hundred pages—is devoted to the revolution in scientific thought during the sixteenth and seventeenth centuries.

It is impossible within the compass of this notice to do justice to the wealth of evidence provided in support of Dr. Crombie's implicit claim that whatever faults there may have been in medieval thought—and he does not deny that there were some—it was certainly not 'stationary'. The twenty pages devoted to bibliography include references to general works in the history of science, more detailed studies of special fields, and a representative selection from the periodical literature in English, French and German. These include numerous modern texts of original medieval sources. The iconographical sources—so important in this period—are represented by twelve plates and fifty text figures: these are admirably selected, and many are from manuscript sources not readily accessible. Something, however, has gone wrong with the legend to Fig. 1 (p. 53), where the Latin would have shocked even the 'Scholastici barbari', and the cosmology represented is 'Aristotle's' only in an Aristotelian sense. Nor, if the examples on p. 138 are a fair sample, is it at all clear what Dr. Crombie means by calling them "excellent": the heart is much too small and placed (conventionally) on the left side of the body, while the representations of the gut and skeleton perhaps bear a slight resemblance to a frog's but none at all to a man's. In the admirably generous and discrete documentation (for a full apparatus of detailed references would be a burden to that 'general reader' whose perusal of the book is so much to be desired) I have found none but comparatively trivial mistakes; but "Principia Mathematica" (1687, not 1686) has an unfamiliar ring in connexion with Newton. One concession to the 'general reader'—the use of the term 'doctor' as a synonym for 'medical man'—is, I suggest, one which, especially during the medieval period, might well have been eschewed.

Not every chemist (nor every mathematician) will be flattered by Dr. Crombie's assertion that "chemistry, like physics, finally set out on its course of being reduced to a department of mathematics"; and at least one reader sees no reason to revise his opinion that, apart from a few exceptional men like Petrus Peregrinus and Theodoric of Freiberg, the medieval thinkers entirely misconceived, as had the Greeks before them, the true nature of experiment. The absence of detailed accounts of the disposal of apparatus and of the control of the sources of error seems to me sufficient proof that it was regarded merely as a means of verification, in striking contrast to, say, Newton's first letter on the "celebrated phaenomena of colours". But if here and there Dr. Crombie's enthusiasm may have outrun his discretion, his book is one which will set a standard for a long time to come. Its publication has removed for ever any excuse there may have been for ignorance of medieval scientific thought.

W. P. D. WIGHTMAN

GRASSLAND CULTIVATION IN BRITAIN

The Grass Crop

Its Development, Use and Maintenance. By Dr. William Davies. (Agricultural Series.) Pp. xiii+318+9 plates. (London: E. and F. N. Spon, Ltd., 1952.) 25s. net.

THE development, use and maintenance of grassland in Britain is a matter of vital national importance—an importance which is becoming more apparent with each pronouncement concerning the national economic position. Faced with the imperative necessity of increasing agricultural production, it is to the grassland that one must look in the main for greater supplies of meat, milk and dairy produce. What is more, grassland represents a vital factor in maintaining soil fertility as well as a means of actually building up fertility, thereby raising the level of corn and root-crop production which is so essential to survival.

The potential of production from grassland rightly cultivated is immense, and the picture is most ably portrayed by Dr. William Davies in his new book, "The Grass Crop", for he himself has been concerned with this crop both in the sphere of research as well as advisory work among farmers for more than thirty years. Allied to his own work on the subject, Dr. Davies, as director of the Grassland Research Station, is in close contact with all the problems of the subject and has widened his canvas by first-hand study in many countries abroad. As a result he has been able to present not only a skilful, scholarly treatise of the subject but also one which will have lasting value to farmers and students alike.

In the early chapters, the historical and ecological aspects of grassland are presented, and Dr. Davies has been successful in weaving into this section much of the philosophy of modern grassland farming. As he so rightly points out, grassland agronomy must have an ecological approach but one not confined to plant ecology, for due heed must be given to both the animal consuming the herbage and the soils producing it. There is, too, the complicating factor of climate which determines the growth of the crop as well as the manner in which it shall be used by the farmer. Thus, the approach to the subject has very wisely been that of the trinity of soil, sward and animal.

Advocacy of the ley system of farming is emphatic and well reasoned, and the target is set at twelve million acres while at the same time retaining the present acreage of field-crops in Britain. The achievement of this goal would enable the sheep population to be doubled and the cattle population increased by more than a third above the 1951 level. But what is more, the attainment of such standards would act as a stimulant to the whole of the agricultural industry. One has only to travel through those counties where the ley is regarded as the pivot of the rotation to realize the salutary effect upon crop production as a whole of the securing of first-class leys.

To accept the principles of ley farming is one thing—to put them into operation is vastly more difficult. So Dr. Davies gives skilled attention to the vital problems of choice of seeds mixture, the establishment of the ley and the influence of the grazing animal on the productivity of the ley as such. A chapter is devoted to a detailed description of the characteristics and agricultural value of the different species and strains of grasses and clovers, and there are chapters on lucerne and the controversial subject of herbs. Seed production, which offers not only a useful additional source of income for many British farmers but is also of vital economic consequence traditionally, rightly merits a special chapter. Particularly valuable are the chapters dealing with permanent grassland and the development of the marginal and hill lands of the country, for it is here that the untapped potential lies and where criticism can so rightly be directed at the conditions found to-day.

The book is completed with an excellent detailed bibliography, covering all aspects of the subject, and also a useful index. It is to be hoped it will have the wide reading public it so richly merits, for apart from the farmers and students for whom it is specifically written, all with an interest in British farmlands, be they geographers, historians or simply lovers of the countryside, will find fascinating and really worthwhile reading in its pages.

H. IAN MOORE

ORGANIC CHEMISTRY FOR THE HONOURS STUDENT

Organic Chemistry

By Prof. E. E. Turner and Dr. Margaret M. Harris. Pp. xi+904. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1952.) 50s. net.

THE writing of a single-volume treatise on organic chemistry inevitably calls for compromise among the rival claims on space arising from a multitude of interests. A purely objective approach is difficult or impossible to maintain, and text-books tend to differ as much in range and emphasis as in arrangement and style. The present authors recognize this: they do not conceal their particular interests, but rather give them prominence in an adequately broad setting. The emphasis is on stereochemistry, and with this deservedly major theme there is interwoven a systematic survey of organic compounds, lavishly illustrated by structural formulæ and enlivened by frequent discussion of reaction mechanisms.

To accommodate the beginner, the first chapter provides a general introduction and sets forth essential features of electrochemical theory. Thereafter the general subject is rationally developed on modern lines, but without neglect of the origin and evolution of modern concepts. Natural products are given representative treatment in separate chapters dealing with carbohydrates, terpenes, steroids, vitamins and alkaloids, while topics such as carotenoids, tropolones, penicillins, anthocyanins and pyrrole pigments are introduced as sub-sections in the general text. Throughout, the aim is to equip the reader for specialist reading and to guide him towards the fringes of current research.

The book provides an excellent refresher course: it will also be widely consulted for its stereochemistry. Although the authors disclaim the intention of writing an examination text-book, the honours student can scarcely fail to find it a profitable study. Yet it requires critical reading, for on occasion the authors reach or imply conclusions which are not strictly warranted by the facts presented. For example, the conclusion that certain optically active alcohols which have the same rotational sign have also the same configuration does not follow from the context on p. 637; nor is it there explained what meaning is to be attached to "same configuration" as applied to benzylmethylcarbinol and ethyl β-hydroxy-β-phenyl-propionate. None the less, the book is written well and in a manner which captures and sustains interest. Despite its size—it is somewhat unwieldy—and the complexity of the formulæ, it is remarkably free from errors of printing. But one cannot commend the practice—here inconsistently applied—of denoting a ring-member by a symbol placed beside the ring-outline as if it were a substituent. In the alicyclic series this is an unsightly and unnecessary elaboration; in the heterocyclic series, where a valency count may not remove the ambiguity, it is a real and avoidable source of misunderstanding.

J. D. Loudon

STRUCTURE-ACTIVITY CORRELATION IN THE MAKING

First Symposium on Chemical-Biological Correlation, May 26–27, 1950

Sponsored by the Chemical-Biological Coordination Center of the National Research Council. Pp. v+415. (Washington, D.C.: National Academy of Sciences/National Research Council, 1951.) 4 dollars.

Since Crum-Brown and Fraser in 1869 ventured to present the relationship between the chemical constitution of a drug (C) and its pharmacological activity (φ) in the form of a pseudo-mathematical equation $\varphi = f(C)$, numerous attempts have been made to verify this relatively simple expression. That these efforts to find a rational basis for drug action have not resulted in overwhelming success is due to various reasons: for example, the meaning of C, the chemical constitution, has often been accepted with superficiality as the two-dimensional formulæ used in chemists' notebooks and not as an integrated collection of all the finer points of physical and chemical properties of the compounds under consideration; differences in the mechanism of action between drugs achieving the same end-effects have been frequently ignored, and the existence of receptor molecules, possessing, like the drugs, specificity of structure and reactivity, has rarely been taken into account; differences in the degree of accuracy between the measurements of biological effects and certain physical-chemical characteristics have been overlooked in many cases.

It is therefore not surprising that, during the past thirty years or so, most of the major advances in the field of biologically active substances have been made by trial and error and by fortuitous discoveries. Yet, here and there, groups of therapeutics were found which were more amenable to a rational treatment, and the emergence of the theory of antimetabolite action has given renewed impetus to the slowly moving searches. But there still remains the necessity for more and more data of biochemical, physicochemical and biological observations, the last-named as quantitative in nature as possible.

To provide such data the United States National Research Council founded in 1946 the Chemical-Biological Coordination Center. With lively optimism, so characteristic of many American undertakings, this body has developed procedures for the collection of data sheets, the preparation of card files and the use of chemical and biological codes. From time to time, accumulated results are published in the form of booklets. True, the chemical data are sometimes scanty and physical-electronic properties more than often missing. The biological results suffer from the fact that they belong to the plus–minus variety; but matters have progressed sufficiently to warrant, in May 1950, the arrangement of the first symposium on simply, perhaps over-simply, expressed "Chemical-Biological Correlation". The lectures and discussions were published during 1951, unpretentiously in varitype print, giving to everyone interested in the subject the chance to see for themselves how matters stand. There are a number of most stimulating contributions, such as that by Schubert on the effect of drugs on physiologically active thiol systems, and by Friedman on the influence of isosteric replacements upon biological activity. Others, experts in various special fields, like Doak and Eagle on arsenosobenzenes, Norman and Weintraub on plant growth-regulators, Lands on sympathomimetics, and Horsfall *et al.* on fungicides, have chosen a defined group of closely related substances to prove their case. Two lectures on antihistamines and antithyroids were used to demonstrate the procedures and the systems introduced by the Center and separately explained by its director, Dr. Kirner, and Drs. Beard and Geer. Two panels were discussing antimalarials and antimetabolites, carcinogenesis and cancer therapy. With regard to the first, one could quote F. L. Rose's statement on the occasion of his Tilden Lecture, "A Chemotherapeutic Search in Retrospect": "... the use of the 'working hypothesis' concept based on observation and the intelligent development of leads . . . must constitute the foundation for speculative research in this field for a long time to come". As to the wide and complex subject of antimetabolites, carcinogens and carcinolytic substances, only the antimetabolites seem to obey certain rules. The rationalization of conditions of cytotoxic compounds is more than ever waiting for the discovery of their true mechanism of action. But this problem, although a very thorny one, and those problems connected with drugs where the mode of action has been more fully elucidated, may yield sooner than expected at present if the attempts at producing and then collecting all pertinent data are vigorously continued; for, as Hales said at the beginning of the eighteenth century, "hardly do we guess aright at the things that are upon earth, and with labour do we find the things that are before us".

F. Bergel

Race Crossing in Man

The Analysis of Metrical Characters. By J. C. Trevor. Pp. iv+45. (Eugenics Laboratory Memoirs, 36. Galton Laboratory, University College, London.) (Cambridge University Press, 1953.) 12s. 6d. net.

CLASSICAL anthropology has been largely concerned with metrical characters such as stature, craniometric characters and the like. The published material on human race crosses has now been sifted and exhaustively and critically summarized in this monograph, which deals with hybrid American Negroes, Jamaican 'Browns', half-blood Sioux, Ojibwa-Whites, Yucatecans, the Rehoboth Bastaards, Kisar Mestizos, the Norfolk Islanders and Anglo-Indians. The data turn out to be surprisingly incomplete. In many cases the racial groups which have contributed to a hybrid population are more or less conjectural. The hybrid groups have thus to be compared with populations which may not represent the ancestors of the crosses at all accurately; this is particularly likely where the European component may have been a small number of individuals. In any event, the ratio in which Europeans and non-Europeans have contributed to a mixed population is usually quite unknown. Some of the measurements on living people with which this monograph deals are notoriously inaccurate, and different investigators may report different values for supposedly the same measurement; in many cases, the parental groups and the mixed population have not been measured by the same worker, at least not on an adequate scale.

Despite all these limitations, two facts seem to emerge as a general rule. Where two parent populations differ significantly for a given measurement, the mixed population tends to occupy a position more or less intermediate between the parental groups. Secondly, for any given character the variability of the hybrid population does not seem to differ strikingly from the variability of the 'pure' races which have contributed to the cross; if there is any difference at all, it is certainly not large. It thus rather looks as if, for the series of metrical characters considered, the parental 'races' have not been appreciably more homogeneous than the mixed populations derived from them. H. Grüneberg

Rocks for Chemists

An Introduction to Petrology for Chemists and Students of Chemistry. By Prof. S. James Shand. Pp. xii+146+32 plates. (London: Thomas Murby and Co., 1952.) 21s. net.

THIS book may be briefly described as an introduction to the study of rocks, their mineralogical and chemical composition, and physico-chemical relationships. The author wishes to convince chemists that the problems of rock and mineral genesis offer a rich field for research.

A short historical introduction is followed by chapters dealing with rocks in the field, rock-forming minerals, the nature of lavas, and the classification of eruptive rocks. The inadequacies of non-chemical classifications and the chemical approach by grouping rocks as oversaturated, saturated, undersaturated, peraluminous, metaluminous, subaluminous and peralkaline are discussed, the limitations of entirely chemical methods of classification being duly stressed. Subsequent chapters deal with plagioclase rocks, dioritic rocks, granitic rocks, syenitic rocks, feldspathoidal rocks and heavy crystal accumulates, the treatment being adequately informative with a definite physico-chemical bias. When appropriate, phase diagrams are used for illustrating the text. Sedimentary rocks are allotted only one short chapter, and the final two chapters deal with metamorphic rocks.

'Multum in parvo' in a quite non-derogatory sense, the book provides a very readable and interesting summary of knowledge and ideas. A section on suggestions for reading is included. The thirty-two excellent plates, illustrating rocks in the field in hand specimens and under the microscope, are well chosen to stimulate interest. C. O. Harvey

On the Metamathematics of Algebra

By Prof. Abraham Robinson. (Studies in Logic and the Foundations of Mathematics.) Pp. ix+196. (Amsterdam: North-Holland Publishing Co., 1951.) 18 f.

THE claim of Couturat, that mathematical logic would help mathematical research, was ridiculed by Poincaré in 1908, who said that logic, so far from lending mathematics wings, had only provided it with fetters. Since that time considerable progress has been made, both in logic and in abstract algebra, and Prof. A. Robinson now claims to have made a positive contribution to the latter subject by the methods of the former. The abstract algebra of fields, rings and similar structure seems more suitable for such treatment than any other branch of mathematics. Two main lines of attack are suggested. Instead of proving individual mathematical theorems, we may be able to show that any theorem of a certain class which is true for one type of mathematical structure is also true for another type. Prof. Robinson claims to have discovered three outstanding results by this method. Alternatively we may be able to develop a theory common to all structures based upon any one of certain systems of axioms, and some progress in this direction is also claimed.

Prof. Robinson's synthesis of algebra and "metamathematics" appears to be a new type of deductive technique which is capable of considerable extension to a variety of applications.

Introduction to Modern Prime Number Theory

By Dr. T. Estermann. (Cambridge Tracts in Mathematics and Mathematical Physics, No. 41.) Pp. ix+75. (Cambridge: At the University Press, 1952.) 12s. 6d. net.

THE object of this tract is to enable mathematicians who are not specialists in the theory of numbers to learn some of its non-elementary results and methods without too great an effort. It assumes no previous knowledge of the subject beyond what is given in Hardy and Wright's "An Introduction to the Theory of Numbers". The tract consists of three chapters. The first deals with Riemann's zeta function and a refinement of the asymptotic formula for the number of primes not exceeding a given integer. The second chapter deals with primes in arithmetical progression, using Dirichlet's L functions, with many theorems on characters. The third chapter deals with the representation of an odd number as a sum of three primes, using the methods of Hardy and Littlewood, and an extension of them by Vinogradoff. The tract concludes with a list of ninety-six theorems and formulæ for reference, and with a very short index. The author seems to have done his best to simplify a difficult subject, but those new to it may be surprised at the complexity of the methods necessary to establish a simple result. H. T. H. Piaggio

AIR MOTION IN THE UPPER ATMOSPHERE

By DR. R. S. SCORER
Imperial College of Science and Technology, London

ON February 6, 1953, a meeting, arranged by the Physical Society, was held in the Department of Meteorology, Imperial College of Science and Technology, London, under the chairmanship of Mr. J. A. Ratcliffe, to discuss the physics of the upper atmosphere. The present article describes, from the meteorologist's point of view, the major problem raised at the meeting.

Before any attempt was made to theorize about the motion of the air at great heights, it was necessary to sample its physical condition. Though it was possible to explain the propagation of the Krakatoa air-wave on the assumption that above the troposphere lay a stratosphere of uniform temperature up to infinity, the reflexion of explosion waves from a height of about 30 km. clearly indicated the existence of a layer in which the temperature increased upwards. This layer is now known to be kept at its high temperature—in places warmer than the air at the ground—by the absorption of a large part of the ultra-violet radiation from the sun by ozone, which is itself produced by this radiation. The ozone dissociates only slowly and can therefore be used as an indicator of the motion of the air at those heights. For example, if a column of air at the ozone levels is elongated vertically the absorption of the ultra-violet is increased: this happens over extra-tropical depressions. Again, the accumulation of ozone over the winter pole, where it is certainly not produced, shows that there is a persistent motion towards that region at the ozone levels. Measurements of absorption by ozone are fairly simple to make, and by comparing the intensity of absorption with the intensity of a nearby wave-length that is not absorbed by ozone when light from the zenith is observed at a large number of times around sunset, a knowledge of the levels from which the scattered light originates may enable an estimate of the vertical distribution of ozone to be made as a routine[1].

The temperature in the ozone layers is a maximum at about 50 km., and above this level it decreases very much as it does in the troposphere, and a minimum of temperature is reached in the region of 80 km. It has been possible[2] to obtain reflexions of radio waves from the *E*-layer, not far above this level, which show that the reflecting layer is not uniform. The non-uniformities are found to move horizontally with velocities of the order of 5–50 m./sec. Similar movements, often with much greater velocities, in one case as large as 1,000 m./sec., have been observed in the non-uniformities of the *F*-layer; but at those levels (around 200 km.) the motion is dominated by electromagnetic and viscous forces and little guidance can be obtained from ordinary dynamical meteorology about the causes of such movements. At levels below 120 km., however, those forces are not predominant in producing the motion of the air, which therefore moves under much the same influences as the air with which meteorologists ordinarily deal—below 30 km. It is of interest to discuss what meteorologists can say about the motion of the air in and below the *E*-layer. Since this layer lies just above the ozone layer, we must first discuss the condition of that layer.

Dynamical Influence of the Upper Atmosphere

Some deductions can be made from observations made at the ground. The semidiurnal pressure oscillation[3] greatly exceeds the equilibrium tide value, and resonance was suggested by Kelvin as the explanation. If the driving force is gravitational, the resonance must be so selective that the lunar tide is not similarly amplified. Two difficulties arise: first, resonance seems to be an incredible fluke; and second, meteorologists are unable to accept that the resonance is so selective. Holmberg[4] has explained how the fluke could have come about. He reminds readers that the pressure surge in the air actually drives the earth round and so overcomes dissipation in the ocean tides and other retarding forces. When, during its evolution to its present state, the rotation was reduced to the speed at which resonance occurred, further slowing down was prevented by this mechanism. The resonance is therefore to be expected and is no more improbable than the monthly rotation of the moon on its own axis, for example.

The second objection is based on the knowledge that the Krakatoa air-wave was greatly distorted by the wind systems in one passage around the earth. The damping is therefore very large for this cause, and the resonance is unlikely to be selective enough to exclude amplification of a larger lunar tide. But we may follow Kelvin and suppose that most of the energy is derived, not from tidal forces but from the temperature oscillations, in which the semi-diurnal component is large. The diurnal variation in amount of cloud and rainfall accentuates the temperature variations, and in many parts of the world there is a nocturnal as well as an afternoon maximum.

The 12-hr. resonant period is not the only possible one, and the 10½-hr. period, if it occurred, would be of much larger amplitude in the troposphere relative to its amplitude in the ozonosphere than the 12-hr. one. Since the energy is mostly put in in the troposphere, why did not the earth cease to slow down when its rotation period was reduced to 21 hr.? Perhaps it was never as small; or if it was, it was at a time when the temperature of the troposphere was much greater. But among other explanations is the possibility that most of the energy is put in in the ozonosphere, where the diurnal temperature variations must therefore be large. The point here is that the upper half of the ozonosphere probably behaves in many ways like the troposphere, and this argument reinforces belief that it does.

Further support is gained from the study of mother-of-pearl clouds. These are thought to form in the lower part of the ozonosphere in the crests of waves produced by the flow of a strong wind-current over a mountain range. In order that such wave motion should occur, the condition of the air at higher levels must be suitable, and one possibility is that the upper half of the ozonosphere is in neutral static equilibrium, that is to say, it is thoroughly stirred by convection currents—as is the troposphere.

Ordinary meteorological observations indicate no influence of the ozonosphere on the weather systems except in a rather indirect way. For example, Palmer[5] suggests that during a solar flare considerable ultra-violet radiation penetrates the ozonosphere and warms the lower stratosphere, with important consequences to the weather. No direct dynamical influence on weather systems other than the two just mentioned has been inferred.

Dynamical Properties of the Upper Ozonosphere

If the motion in the troposphere were the same as the mean motion, it would be unstable. The nature of the instability, which can be studied theoretically, and which we will refer to here as the 'cyclone type', gives a clue to the mechanisms operating in the disturbances which are the departures of the actual motion from the mean motion, and there is reason for believing that these operate in a similar manner in the upper ozonosphere. But the results would be somewhat different. In the first place, there is no rigid boundary, and this would make it less likely that sharp surfaces of discontinuity of temperature and velocity, known as 'fronts' in the troposphere, would be generated. Another effect due to the earth's surface is that the diurnal variations of temperature occur mainly over the land, which forms only a small part of it. Heat is communicated to the air by convection currents from the surface. This convection goes on day and night over the oceans, while in the ozonosphere the heat is absorbed over a great depth of air—effectively perhaps 20 km.—and is all taken in during the hours of sunshine. It is to be expected, therefore, that the convection currents, which shall for convenience be called the 'cumulus type', would be on a much larger scale, geometrically, the largest being indistinguishable from the cyclones and anticyclones generated by the other mechanisms, while diurnal variations (in which are included the semi-diurnal) would be much more in evidence.

A static picture of the state of the atmosphere at these levels has been usually presented. In the troposphere and lower stratosphere, we know that the variations are very great and that at any one moment the temperature is very different from its average value. There is a continual exchange of air between the troposphere and the stratosphere by means of the disturbances of the cyclone and anticyclone type, although ordinary convection is restricted to the troposphere. Any vertical temperature gradients in the ozonosphere that may be measured cannot be taken as representative because there is no single state to represent. There is almost certainly a vigorous exchange of air, of a type that is hybrid between the towering cumulus and the cyclone, between the ozonosphere and the levels of the *E*-layer by means of convection currents, and these would presumably produce variations in the ionization concentration in the *E*-layer.

Meteorologists cannot at present be expected to develop the mathematics of these convection currents, for the theory of the disturbances we can readily observe in the troposphere is very rudimentary and observations are completely lacking in the ozonosphere. It is here that the observations on the size, diurnal variation and movements of the irregularities of ionization can help, for if they are due to these motions a scale can be set for them and we can begin to theorize.

Interpretation of Observations

Now that a fairly long series of observations on the movement of the irregularities is being accumulated, it is worth while to do more than speculate about the meaning of these movements. At first they were interpreted as winds, that is, bulk movements of the air as a whole. The daily variations first found at Cambridge have not been exactly repeated either at Washington or at Cambridge in another season, and obviously more observations are required before we can decide whether the supposition that the movements are winds is reasonable. We know that the diurnal influences are very strong; but a regular daily cycle of wind reversal is not what meteorologists would expect on the basis of observation of the air lower down, except that the semi-diurnal oscillation would be large at these levels; but that would not interfere with the convection and other circulations. This does not mean that the movements are not winds, but that we cannot easily be satisfied that they are; no meteorologist would be dogmatic at present.

The possibility that they represent some kind of inertial gravity wave motion transmitted through the air must be ruled out until an energy source for the wave motion has at least been suggested. Because of the enormous variety in wave-lengths and velocities that could be transmitted by the air, it is possible to 'explain' almost any motion in terms of waves so long as the wind velocity is not known, because the wave velocities depend so much on the wind structure.

If the movements are not of air but of ionization density, a cause for the non-uniformity may nevertheless be sought in the inhomogeneity of the air. The atmosphere is certainly well stirred up to 100 km. and probably higher by ordinary meteorological mechanisms; but since convection is the mechanism for the stirring, the inhomogeneities are on the scale of the convection. The inhomogeneities are mainly of ozone, water vapour and temperature (that is, density); whether these can produce variations of ionization of the observed kind is not for the meteorologist to say. When the irregularities have been created by air movements, they may yet follow a path dictated primarily by electromagnetic forces.

At much greater heights, in the *F*-layer, irregularities also appear and are similar in many ways; but the medium, being so rare and so highly ionized, does not behave like the fluid with which meteorologists ordinarily deal.

Conclusion

Observations, direct and indirect, indicate a mean profile of temperature with a maximum around 50 km. and a minimum around 80 km. In many respects the dynamical properties of the layer between are likely to be similar to those of the troposphere; but there are significant differences, the chief of which are the dominance of diurnal variations and the greater size of the convection elements. The actual temperature at any place and time probably differs greatly from the average, and it is the variations which are associated with the important dynamical processes.

At present, the only frequent observations being collected are the movements of the irregularities in the *E*-layer; and meteorologists hope that there is a connexion between them and air movements, however indirect, so that they will throw some light on the scale of the motion.

A NEW AGRICULTURAL RESEARCH INSTITUTE

GLASSHOUSE CROPS, MUSHROOMS AND OUTDOOR FLOWERS AND SHRUBS

By DR. E. E. CHEESMAN
Agricultural Research Council

ON the advice of the Agricultural Research Council, the Minister of Agriculture is founding an independent Agricultural Research Institute to promote research on the cultivation of glasshouse crops and mushrooms and of bulbs, flowers and shrubs grown commercially in the open. The announcement marks another step in the evolution of the Agricultural Research Service, and there is interesting history behind it (see also *Nature* of July 18, p. 89).

Forty years ago a group of nursery growers in the Lea Valley north of London were alarmed by the losses caused by pests and diseases on glasshouse crops and realized the need for research to be directed upon means of control. They formed the Nursery and Market Garden Industries' Development Society, Ltd., and, assisted by grants from the Ministry of Agriculture and from three local county councils, started a small experimental centre at Cheshunt.

The venture quickly proved its value, and acquired a reputation more than local. In 1923 the Ministry of Agriculture increased its grant to allow for increase of staff and more laboratory accommodation, on condition that the centre should extend its services beyond the Lea Valley to the glasshouse industry of the whole of Britain. The Experimental and Research Station, Cheshunt, then began to take the form it has to-day. The field of investigation widened to include studies of glasshouse soils with particular reference to the effects of partial sterilization by steaming or other methods, the physiology of glasshouse crops, and new techniques in glasshouse practice generally. The contributions of the Station, under the direction of Dr. W. F. Bewley, to increased production under glass have been set out in a series of annual reports, of which thirty-seven have been published.

When, after the Second World War, the National Agricultural Advisory Service was established, the Station, like other research institutes of similar origins, found itself relieved of direct advisory responsibilities to growers and freer to concentrate on the fundamental scientific questions that underlie the day-to-day practical problems of the industry. It was, however, not equipped to take full advantage of the change in emphasis.

By this time the facilities at Cheshunt had become inadequate for a national glasshouse research station. The Lea Valley had changed in character; the site was hemmed in by urban development and critical work was handicapped by the atmospheric pollution associated with the growth of Greater London. A move that would have been inevitable in any event was made more urgent by damage sustained by the Station during the War, which left the experimental glasshouses in bad condition.

A group appointed jointly by the Agricultural Research Council and the Agricultural Improvement Council to survey the post-war needs of research in the various branches of horticulture recommended that a new site should be found for glasshouse research, and that the opportunity should be taken to couple with it research into other commercial nursery crops for which no central facilities have hitherto existed, especially flowers grown out of doors.

A long search began for a site combining all the necessary features, one of which is proximity to an important local glasshouse industry. It ended recently with the acquisition of a hundred acres of land at Toddington, near Littlehampton, Sussex. Here the new Institute will begin its work with staff and apparatus transferred from Cheshunt and will have room to extend the Cheshunt programme in several directions.

The better light conditions for which the Worthing district is famous will make possible many studies of plant growth under glass on a scale hitherto impracticable. There is, for example, a promising field in the exact definition of the light and temperature requirements of glasshouse crops, which are known to vary between different varieties and at different stages of development for each variety. With facilities for critical experiments, the new Institute will be able to collaborate more effectively with the National Institute of Agricultural Engineering, which is working on glasshouse design and the control of glasshouse climate and so seeking to find the means of meeting the requirements of plants economically.

In developing new lines of inquiry, the Institute will not abandon the old, for the war against pests and diseases under glass still remains of major importance, and the study of new weapons and tactics deserves the better facilities that will be provided.

OBITUARY

Mr. C. D. le Maistre, C.B.E.

SOME men achieve fame for the number of important jobs they have held; others, like Charles Delacour le Maistre, achieve their ambition by sticking to the same job throughout their working life, building up an organization or a movement from practically nothing to a mature and steadfast entity. The cause built up by le Maistre is that generally referred to as 'industrial standardization'; it has world-wide ramifications, and the national standards bodies set up in more than thirty different countries are directly or indirectly modelled on the British Standards Institution, which, in its earlier years, was built up under le Maistre's supervision. Born in Jersey in 1872, trained as an electrical engineer in South Kensington, he joined the small staff of the Engineering Standards Committee in 1902 and became its secretary in 1916, a post he retained until 1929. In that year the British Engineering Standards Association (the successor to the Engineering Standards Committee) received its Royal Charter, and le Maistre was appointed director. He was thus at the helm when the Association again changed its name, this time to the British Standards Institution, in 1931, and he finally retired from the Institution in 1943, having served as chairman of the Executive Committee during the year 1942–43.

Le Maistre's work in the international sphere, and still in the field of standardization, covered an even longer period, for he was appointed general secretary of the International Electrotechnical Commission on its formation in 1904 and still held that post at the time of his death, on July 5. He became seriously ill, for the first and last time in his energetic life, a few months ago, thus having to cancel his plans for motoring to Yugoslavia for the meetings of the International Electrical Commission which were held in that country at the end of June. It was a great disappointment to him that for the first time in all these years he had to miss a meeting of the Commission. It will also be a cause of great regret to his many friends throughout the world that le Maistre has died before the jubilee celebrations of the Commission which are being planned for Philadelphia in 1954. He died just before he could be informed of the decision of the Commission to institute an annual lecture to be known as the Charles le Maistre Lecture, to be given by prominent personalities in the field of international standardization.

Charles le Maistre was a member of Council of Aslib for many years, and its chairman during 1949–50. During his association with Aslib, he became interested in the work of the International Federation for Documentation, and it surprised no one but himself that he very soon found himself elected president of the Federation, a post which he held with great distinction from 1946 until 1951.

He joined the Institution of Electrical Engineers as an associate in 1897 and became a full member in 1908. He was an associate member of the Institution of Civil Engineers, a member of the American Institute of Electrical Engineers, and a fellow of the City and Guilds Institute. He had served on the Council of the Institution of Electrical Engineers, and for his services in connexion with standardization during the First World War le Maistre was awarded the C.B.E. Among the foreign honours bestowed upon him were the knight commander (second degree) of the Royal Swedish Order of Vasa, honorary membership of the Royal Dutch Institution of Engineers and, quite recently, he was made a chevalier of the Legion of Honour (France).

Long after most men of his age would have claimed a well-earned rest after so active a life, le Maistre continued to thrive on work and he was constantly making journeys all over the Continent on behalf of the International Electrotechnical Commission or the International Federation for Documentation. When not abroad he regularly played squash, an energetic game even for a far younger man, and he devoted many of his leisure hours to his beloved bees. He took his hobby seriously and was chairman of the Surrey Beekeepers' Association during 1946–47.

Le Maistre had the happy knack of drawing the best out of all his colleagues, and his steadfastness of purpose earned him the respect of all with whom he came into contact. He firmly believed in his mission, not for the sake of standardization itself, but because he was convinced that the only salvation for mankind was the creation of a spirit of real understanding between individuals and between peoples, and the work on which he was engaged was a step in that direction. The foundations on which this work is now forging ahead in all parts of the world were indeed soundly laid by that pioneer Charles Delacour le Maistre.

J. F. STANLEY

NEWS and VIEWS

The Drummond Memorial Fund

WITH the object of commemorating the name and work of Sir Jack Drummond, who, together with Lady Drummond and their daughter Elizabeth Anne, were murdered on August 4 (see *Nature*, 170, 229, 401; 1952), a Committee has been formed under the chairmanship of Lord Woolton, and over Lord Woolton's name an appeal has been issued. The members of the Committee are Lord Horder and Prof. E. C. Dodds, representing medicine; Sir Harold Himsworth, secretary of the Medical Research Council; Sir William Slater, secretary of the Agricultural Research Council; Dr. Norman Wright, of the Ministry of Food; Profs. A. C. Chibnall, G. F. Marrian and F. G. Young, representing biochemistry; Mr. Leonard Anderson, Dr. H. J. Channon, Sir Harry Jephcott and Mr. Wilfred Vernon, representing industry; and Dr. Ifor Evans, provost of University College, London. The Committee considers that the most suitable memorial would be an endowed Drummond Research Fellowship dealing with Sir Jack's main interest, namely, nutrition. A fund of about £25,000 is required, which will be administered by a body of university trustees, and the Fellowship will be tenable at any university or appropriate research institute. Subscriptions, whether by gift or covenant, should be addressed to the Drummond Memorial Fund, c/o Westminster Bank, Ltd., 154 Harley Street, London, W.1.

Applied Mathematics at Nottingham: Dr. Rodney Hill

THE Department of Mathematics at the University of Nottingham is expanding, and from the beginning of the 1953–54 session will include a professor of applied mathematics in addition to the professor of pure mathematics. Dr. Rodney Hill, now Research Fellow in theoretical mechanics in the University of Bristol, has been appointed to the new chair. His appointment at the early age of thirty-two is a fitting testimony to the outstanding work he has done in the relatively new and difficult field of mathematical plasticity. Dr. Hill graduated at Cambridge in 1941, and after a period spent in research there he joined the theoretical branch of the Armament Research Department. He returned to Cambridge after the War and worked there until 1948, when he became head of the Solid Mechanics Section of the British Iron and Steel Research Association laboratory at Sheffield. During his stay there he accomplished some notable work on the rolling and forming of metals. In 1950 he was appointed Research Fellow in theoretical mechanics in the University of Bristol, and there he collaborated with others engaged on theoretical and experimental investigations. His contributions to the theory of plasticity are contained in some thirty papers which he has written since 1945, either alone or in collaboration with others, and in a book, "The Mathematical Theory of Plasticity", published in 1950. This outstanding book is likely to remain for some time to come the standard work on the foundations of the subject. Last year he was appointed joint editor of the new international *Journal of the Mechanics and Physics of Solids*. The University of Nottingham can look forward to a period of development in applied mathematics and to the formation of close and valuable links with industrial research in Dr. Hill's field.

Notes and Records of the Royal Society

The recent appearance of the April number (vol. 10, No. 2) of *Notes and Records of the Royal Society of London* provides an opportunity of directing general attention to this valuable periodical. Hitherto addressed mainly to Fellows, it has gradually established itself as a medium for the publication of full articles on less well-known past Fellows, and also of more detailed notices of discoveries, which have cast a new light upon already well-documented lives. With the current issue the editor is circulating an appeal to Fellows to widen the search for MS. material and to enlist the interest of others who may be engaged on research into the history of the Society or of its past Fellows. The current issue, besides containing reports on the anniversary dinner and the Ramsay centenary, naturally emphasizes Sir Hans Sloane, the bicentenary of whose death falls this year. An article on Samuel Hartlib's influence continues the valuable series of studies, by various authors, of the circumstances of the foundation of the Royal Society. Those whose interests are rather literary than scientific will also do well to keep an eye on *Notes and Records*: in the current number Dr. Johnson's scientific affinities are shown to have been greater than is commonly realized, and M. de Voltaire appears in an engaging light in the "Journal" of John Morgan, an American Fellow. Following an account of the outstanding Keynes Collection of Newtoniana in the previous issue, we are in the current one provided with a concise but fully catalogued summary of the archives of the Cavendish Laboratory. *Notes and Records*, indeed, seems admirably adapted to become one of the much-to-be-desired meeting grounds for devotees both of the natural sciences and humanities. In its finely printed pages historians will scarcely fail to find valuable material; and others, less pragmatically, perhaps even more valuable entertainment.

Irish National Committee for Geodesy and Geophysics

An Irish National Committee for Geodesy and Geophysics was established in 1952 with headquarters at 44 Upper O'Connell Street, Dublin. The Committee was established in accordance with the recommendation of the International Union of Geodesy and Geophysics, of which Ireland, through the Department of Industry and Commerce, has been a member since 1939. The Minister for Industry and Commerce, Mr. Sean F. Lemass, appointed Mr. J. C. B. MacCarthy, of the Department of Industry and Commerce, to be chairman of the Committee. Represented on the Committee by one member, whose name is given in brackets, are the following institutions: Irish Meteorological Service (Dr. M. Doporto); Royal Irish Academy (Prof. J. J. Dowling); Seismological Observatory, Rathfarnham Castle (Rev. R. E. Ingram, *S.J.*); University College, Cork (Prof. J. J. McHenry); St. Patrick's College, Maynooth (Rev. P. J. McLaughlin); Ordnance Survey (Lieut.-Col. J. E. Nolan); University College, Dublin (Dr. P. J. Nolan); Geological Survey (Mr. M. V. O'Brien, director of the Survey); University College, Galway (Prof. C. O. Brolchain); Department of Agriculture (Mr. S. O. Meallain); Dublin Institute for Advanced Studies (Prof. L. W. Pollak); Trinity College, Dublin (Prof. J. H. J. Poole). The Committee meets about four times a year, and the matters which have so far engaged the attention of the Committee include hydrography, the Irish bibliography for hydrology, geodetic levelling and methods of accurate computation of mean sea-level for Ireland. The means by which the Committee can most effectively discharge its functions have been under consideration, and the Committee or individual members thereof will welcome communications from scientific bodies or persons interested in any of the branches of science covered by the International Union.

Botanical Society of Bengal

The seventeenth annual general meeting of the Botanical Society of Bengal was held on May 16 in the Department of Botany, University of Calcutta. Dr. R. Ahmed, Minister for Agriculture and Co-operation, Government of West Bengal, who was chief guest, spoke on the difficulty of inducing the Indian farmer to adopt the seeds, manure and equipment developed as a result of modern research. Consequently in India there is a great gap between the scientist in his laboratory and the worker in the fields. Dr. J. C. Sen Gupta, president of the Society, spoke of "Some Aspects of Recent Studies on Plant Growth Substances". In his review he recalled the considerable improvements in the field of agriculture, made possible by the application of particular hormones at particular stages in the life-history of the plant. Some recent discoveries of certain growth-substances of root, stem, leaf and flower have been utilized in such varied aspects as the increase of fruit yield, the induction of seedless fruits, the causing of biennially fruiting trees to bear annually, the defoliation of plants, the prevention of leaf-fall, the control of weeds and the like.

Sjta. Mridula Datta, hon. secretary, presented the annual report of the Society. During the year greater interest has been aroused by holding the meetings at different centres of botany. Consequently the membership has increased. Two issues of the *Bulletin* have been published. The following officers were elected for 1953–54: *President*, Dr. J. C. Sen Gupta; *Hon. Secretary*, Sjta. Mridula Datta; *Hon. Treasurer*, Sri P. K. Bose; *Editor of Publications*, Prof. S. R. Bose; *Secretary Foreign Correspondence*, Sri A. K. Ghosh: *Hon. Librarian*, Sri J. K. Sen.

Specifications for Insecticides

The World Health Organization Expert Committee on Insecticides devoted its fourth session to a general revision of specifications for substances used in controlling insect vectors of disease. The report on this session appears as No. 54 in the World Health Organization Technical Report Series (pp. 94. London: H.M.S.O., 1953. 5*s*.). New standards have been adopted for the following insecticides: technical DDT, technical benzene hexachloride (BHC) and its concentrates, technical methoxychlor, technical chlordane, water-dispersible powder concentrates of DDT and of BHC, and DDT emulsion concentrates. Technical dieldrin, pyrethrum extract, and certain emulsion concentrates were among other substances considered for which standards were formulated. Throughout this work the committee was at pains to specify only one test method—the simplest possible—for the determination of a given property. Although it is as yet unable to recommend a single control-test for the determination of sedimentation-rates for most water-dispersible powders, it has perfected such a test for the dispersible-powder forms of DDT. Specifications for aerosols, diluents, solvents and emulsifiers, as well as certain data on the preservation of insecticides under various climatic conditions, are also given in the report. In addition to the description of test procedures, the annexes contain sampling instructions, and an account of a provisional method for testing aerosols which has been successfully employed in the United States of America. For those—whether manufacturers or buyers—who are obliged to keep abreast of the latest developments in this field, this report is a valuable source of information.

Register of Specialist Indexers

To assist authors and publishers in achieving a high standard of indexing in their published works, Aslib (formerly the Association of Special Libraries and Information Bureaux) is establishing a register of specialist indexers. The register will consist of persons who are available for part-time indexing only; a staff employment register is already maintained for indexers and other library staff seeking full-time employment of either a temporary or permanent nature. Indexers will be enrolled in two categories: those who can produce evidence of indexing ability, and those who appear to possess the necessary qualifications but who have no published indexes to their credit. In both cases, evidence of special knowledge of one or more subjects will be required, so as to ensure competence in handling technical and other specialized material. All indexing work negotiated through the Aslib register will be subject to scrutiny and report as a means of ensuring that the register becomes and remains a recognized source of reliable subject indexers. Inquiries should be addressed to the Director, Aslib, 4 Palace Gate, London, W.8. Under the terms of the register, which is licensed annually by the London County Council, no charge will be made to employers but a small enrolment fee and commission will be charged to those indexers who are accepted for enrolment, unless they are personal members of Aslib, when no charge will be made.

High-Altitude Research Laboratory in Alaska

A PERMANENT high-altitude observatory for research in cosmic radiation, high-altitude biology, and meteorology is in the course of being established on the summit of Mt. Wrangell (14,006 ft.), a dormant volcano in Alaska, by an expedition led by Dr. Serge A. Korff, professor of physics in New York University, and Dr. Terris Moore, president of the University of Alaska (see *Nature*, June 27, p. 1140). It has now been announced that a party of five has climbed the mountain on foot, arriving at the summit on July 1. It included Arthur Beiser and Hugo Neuburg, graduate students of New York University; Charles Wilson, of the University of Alaska; Philip Bettler, of the Geophysical Institute; and Robert Goodwin, of Anchorage. They were the second group ever to reach the summit, the first successful ascent having been made in 1908. Two Jamesway huts and related supplies and equipment have been dropped to the party by a private plane piloted by Dr. Moore. One of the huts is used as living quarters by the research workers; the other is a laboratory housing scientific supplies and equipment.

Solar Variation and Precipitation at Peoria, Illinois

A PAPER entitled "Solar Variation and Precipitation at Peoria, Illinois" has been published by Dr. C. G. Abbot (Smithson. Misc. Coll., 117, No. 16; Sept. 3, 1952), in which he returns to the subject of twenty-three periodic changes in the intensity of the solar radiation, a problem to which attention has already been directed (Smithson. Misc. Coll., 117, No. 10; 1952). Dr. Abbot has been engaged for more than three years in investigations of precipitation records between 1856 and 1939, and in the present paper shows that periodicities of the same length as nineteen of those discovered in solar variation are accompanied by changes of 5–20 per cent amplitude in the precipitation at Peoria. Four graphs show how these periodic variations of precipitation occur in nearly equal amplitudes and with moderate differences of phase in twelve separate independent intervals, each several years long. Using these results as a basis, predictions of the precipitation for Peoria during 1940–50 are made and the results are very satisfactory. The actual precipitation ranges from 50 to 150 per cent of normal, and prediction matches the event for eight out of eleven years to within an average deviation of 14·7 per cent. Large fluctuations in precipitation during the other three years were matched by similar large fluctuations in the curve of prediction, but with phase differences varying from three to six months. It is admitted that it is difficult to understand how solar changes generally less than 0·2 per cent can produce variations in precipitation of 5–20 per cent; but, in spite of this, these periodic changes of precipitation have been synthesized to forecast seasons. One of the graphs in the paper shows the predicted precipitation at Peoria during 1940–50, and for the first three years there is fair agreement between prediction and event; but after 1942 there was change of phase, though not of form, and changes of phase mar long-range predictions. Dr. Abbot adds at the end of the paper that, unless the phase-changes can be anticipated, the method of prediction fails to come up fully to expectation.

Library of the University of Leeds: Annual Report

THE annual report of the librarian of the University of Leeds for the session 1951–52 (pp. 16; 1952) records holdings on June 30, 1952, of 351,847 books and 155,278 pamphlets; accessions during the year numbered 14,130 and 3,564, respectively, and, compared with the first year of the quinquennium just ended (1947–48), the total stock increased by 20 per cent and annual accessions by 28 per cent, due partly to increased book funds, especially in the form of non-recurrent grants from the University Grants Committee and from the Council. The rate of additions to the catalogue increased by 144 per cent, and the growth of the main author catalogue presents a serious problem of accommodation. Binding increased in bulk by 62 per cent and is now limited chiefly by finance. The annual number of loans increased by 56 per cent, and inter-library loans were developed as a matter of policy; the Library borrows extensively from other libraries in the region and throughout Britain and abroad, and lends extensively in return, especially to other universities and to public libraries in the Yorkshire Regional Library System. Hopes that during the new quinquennium a systematic effort could be made to fill some of the more serious gaps in the collections are unlikely to be realized, and it is probable that a main concern will be to avoid an undue decrease in the intake of current publications in view of the constantly rising cost of books. The successful display of French scientific publications was followed in January 1952 by an equally successful exhibition of Dutch learned publications.

Physics of Fibrous Materials: Symposium in Arnhem

A symposium on the physics of fibrous materials was held under the auspices of the Dutch Physical Society during October 5–6, 1950, at Arnhem. The original intention to publish the proceedings of the symposium in the *Nederlands Tydschrift von Natuurkunde* proved impracticable; but, with the assistance of the editors of *Rayon Revue*, a report in English has at length been published ("Physics of Fibrous Materials". Pp. 107. Arnhem: N.V. International Rayon-Verkoopkantor). The illustrated booklet contains the introduction to the symposium delivered by P. H. Hermans, the chairman of the symposium committee, and nine papers as follows: fibrous materials from the physical point of view (J. M. Goppel); X-ray diffraction analysis of fibrous materials (A. Weidinger); deformation mechanisms (P. Dekking); longitudinal abrasion of elementary filaments (V. E. Gonsales, the secretary of the symposium, this paper being a shortened version of an article in the *Textile Research Journal*, 20, 28; 1950); behaviour of fibres as they glide (H. L. Röder); physical problems in textile research (J. R. H. van Nouhys); determination of the irregularity of slivers, rovings and yarns (F. H. Germans); high-frequency drying in the rayon industry (R. van Nes); and drying of textile materials with the aid of infra-red radiation (H. J. Selling). Brief discussions are appended to each paper.

Classification of Rubber Literature

A revised system of classification of information on rubber has been agreed upon jointly by the Research Association of British Rubber Manufacturers, the Rubber-Stichting, Delft, and the Institut Français du Caoutchouc, Paris, for use by all associated institutions in Europe and in the Far East. The system, which is primarily a classification by material and not by article of manufacture, is based on the classification used in the monthly periodical, *Rubber Abstracts*, of the Research Association of British Rubber Manufacturers; and this body has issued, as Information Bureau Circular No. 410, a copy of the system, printed as duplicated sheets, which is obtainable on application to the secretary (105–7 Lansdowne Road, Croydon, Surrey). It is proposed eventually to issue the system in a printed form, and also in French and German versions, together with an index, now in preparation; but librarians and rubber technologists are invited to submit comments and suggestions before it is committed to print.

An Orchid Flora of Guatemala

The "Flora of Guatemala", by P. C. Standley and J. A. Steyermark, is being published by the Chicago Natural History Museum over a period of years. The first volume of the "Orchids of Guatemala", by Oakes Ames and Donovan Stewart Correll, has now appeared (*Fieldiana*: Botany, 26, No. 1). The second volume is promised for the near future. Guatemala, with some eight thousand species of vascular plants, is a very rich and varied floristic region and has long been recognized as a happy hunting ground for orchid collectors. A large number of species has now been recorded. During the period 1938–42, Standley and Steyermark, as part of a general collection, collected some 323 species and 19 varieties of orchids, distributed among 68 genera, of which 3 genera, 38 species and 4 varieties were new to Guatemala and 8 species were new to science. In all, some 527 species in 89 genera have been recorded in Guatemala. This new orchid flora contains an introductory essay in which the authors point out that the wet rain forests of Alta Verapaz, with abundant rainfall all the year round, have yielded some 242 species in 60 genera of orchids, as well as many Bromeliaceæ. The rain forests of the Atlantic coast are also rich in orchid species. The distribution of orchids in the several floristic regions is briefly indicated. The largest genera in Guatemala are *Epidendrum* (87 species), *Pleurothallus* (55 species), *Spiranthes* (35 species), *Oncidium* (33 species). Some 57 species in 23 genera occur only in Guatemala; but only one monotypic genus is known to be endemic there. Some species are found at high altitudes, up to 13,000 ft. Keys to the tribes, genera and species are given, and many species are illustrated by line drawings.

Ascospore Dimorphism

An account has been given by M. J. Mathieson (*Annals of Botany*, N.S., 16, 64; 1952) of ascospore dimorphism and mating type in *Chromocrea spinulosa*. The asci contain four large and four small ascospores, each two-celled, arranged in the six patterns expected if spore size were controlled by a pair of allelic genes, the locus showing 65 per cent second-division segregation. The small ascospores produce sterile colonies, the large ones moderately fertile colonies, the asci of which again show segregation for spore size. Fertility is stimulated where colonies from large and small spores meet. In crosses of various mutants with the wild type, all asci in perithecia developed along the line of junction show segregation for the mutant as well as for spore size. Evidently *Chromocrea* is heterothallic, the spore-size difference being a pleiotropic expression of mating type. One allele, that governing large spores, occasionally mutates to the other allele, resulting in fertility of colonies from large spores.

Stories in Hair and Fur

A temporary exhibition arranged by the Cranbrook Institute of Science, U.S.A., to illustrate the sources and biology of hair and fur and man's uses of them for protection and other purposes has been transferred to Britain for circulation by the Museums Association (Meteorological Buildings, Exhibition Road, London, S.W.7). The cost of bringing the exhibition across the Atlantic and printing booklets and posters was met by the Fur Trade Information Centre. The exhibition consists of thirty-one panels designed to be hung on open screens (except in the case of thirteen which require the protection of glass or a handrail) and supplementary skins.

Technical Certificate of the Museums Association

The Museums Association has now approved finally the details for the establishment of a certificate for proficiency in technical matters. The drawing up of a scheme has proved a difficult task, not least in avoiding misunderstanding as to its purpose caused by the widely different ways in which the term 'technical' is employed in describing museum posts. The certificate will be given for competence in the preparation, restoration and practical display of museum exhibits, including natural history, archæological and geological material, water-colours, drawings, prints, frames, ceramics, glass, furniture, metal-work, costumes, needlework, and textiles. It is hoped that in the future it may be possible to arrange special training courses for candidates; but at present it is assumed that they will obtain the necessary knowledge and experience in the course of their normal duties. Other than the registration and examination fees, the candidate will not be liable for any other expenses.

Grants for Research in Experimental Psychiatry

The Rockefeller Foundation of New York has made a grant of £28,800 to the Department of Experimental Psychiatry, University of Birmingham, for research in psychiatry, and the biochemistry and pharmacology of the nervous system. The department was founded in October 1951. Its aim is the application of experimental method to problems of clinical psychiatry. The problems under investigation at present are essentially neurochemical and neuropharmacological. It is, however, hoped to develop systematic studies into the preventive and social aspects of psychiatry as well. An Early Treatment Centre (comprising in-patient, day-patient and out-patient facilities) is being planned, and should, when complete, provide a suitable setting for studies of this kind.

Government Grants for Nuclear Research in Sweden

The Government of Sweden has announced that it is making grants totalling Kr. 1,500,000 (that is, about £100,000 or 300,000 dollars) to be spent during the budget year of 1953–54 on nuclear research in Sweden. Among the various kinds of research for which the money is intended are included the following: additional grant for the building of a Van de Graaff generator at the University of Lund; costs for the operation of the high-tension laboratory of the Karolinska Institutet, Stockholm, and for emanation experiments at the same institute; research into the beta- and gamma-radiating elements stored in the human body; synchrotron laboratory experiments and electronics experiments at the Tekniska Högskolan in Stockholm; and other aspects of nuclear chemistry and nuclear physics at various institutions.

Chemical Engineering Conference

The Institution of Chemical Engineers and the Chemical Engineering Group of the Society of Chemical Industry are organizing a Chemical Engineering Conference to be held during September 7–11, at Olympia, London, at the time of the Engineering, Marine and Welding Exhibition and the Chemical Plant Exhibition. The Conference will be open to all visitors to the Exhibition. The programme includes papers on carbon and graphite as materials of construction for chemical plant, production and properties of tantalum and zirconium, developments in the production of chlorine with special reference to mercury cells, recent advances in milk processing plant, evaporation with particular reference to heat-sensitive liquids, recent advances in distillation, production of formaldehyde from methanol by the silver catalyst process, and application of plastics to chemical plant. There will also be a discussion on British chemical engineering in the light of recently published reports, to be opened by Sir Harold Hartley and Mr. J. Grange Moore.

Seventh Congress of the International Scientific Film Association

The seventh congress of the International Scientific Film Association will be held during September 18–27 in the National Film Theatre and Royal Festival Hall, London, S.E.1. During this period there will be meetings of the general assembly of the International Scientific Film Association, of the permanent committees dealing with medical, research, technical and industrial films, as well as the usual Festival of Scientific Films. A special committee of the British Scientific Film Association will consider and recommend films for submission to the Festival; full details of films should be sent, including title, running-time, gauge, date of production, brief synopsis, etc. In addition, the Association would be glad to have details of research and record films of specialized types, which need not necessarily be in the form of complete titled 'films', for showing at meetings of the permanent committees dealing with medical, research, technical and industrial films. Special meetings and film shows will be devoted to the technique and application of films in medicine; further particulars may be obtained from the vice-chairman of the Medical Committee, Dr. R. C. MacKeith, Guy's Hospital, London, S.E.1. Information about the Congress as a whole can be obtained from the General Secretary, Scientific Film Association, 164 Shaftesbury Avenue, London, W.C.2.

Science and Applications of Photography

An international conference on the "Science and Applications of Photography" is being organized by the Royal Photographic Society of Great Britain and will be held at the Institute of Education (London University), Malet Street, London, W.C.1, during September 19–25. The provisional programme includes public lectures by Dr. C. E. Kenneth Mees and by Dr. R. M. Evans, Color Control Division, Eastman Kodak Company, both to be delivered at the Royal Institution, Albemarle Street, London, W.1, and five sessions of sections for the presentation of papers and for discussion. Membership of the Conference is open to all; the fees are, for members of the Society and lecturers £1 1*s*., and for non-members £2 2*s*. This includes one set of preprints of the papers presented in any one of the five sections of the Conference; preprints of papers in other sections can be obtained on payment of an additional 5*s*. for each section. The full text of the papers will also be available in microfilm or similar form. Further particulars can be obtained from the Secretary of the Royal Photographic Society, 16 Princes Gate, London, S.W.7. The annual congress of the International Scientific Film Association is being held in London during approximately the same period, and reciprocal arrangements are being made to enable members of each to participate in the activities of the other, without additional fees.

Third International Congress of Electroencephalography and Clinical Neurophysiology

The Third International Congress of Electroencephalography and Clinical Neurophysiology will be held in Boston at Agassiz House, Radcliffe College, Cambridge, Mass., during August 16–21. Besides the scientific sessions there will be six symposia on, respectively: recent developments in electroencephalographic techniques; the physiological basis of the encephalogram; the interpretation of the encephalogram; evaluation of activation of the electroencephalogram; interrelationships between cortex and sub-cortical structures; and characteristics and significance of seizure discharges. Further information regarding the Congress can be obtained from the secretary-general, Dr. Robert S. Schwab, Massachusetts General Hospital, Boston 14, Mass.

Fourth Anglo-American Aeronautical Conference

The Fourth Anglo-American Aeronautical Conference will be held in London during September 15–17. The subjects of papers to be discussed include the control of flight, structure of high-speed aircraft, fatigue of aeroplane structures, helicopter design, pod mounting of turbo-jet engines, boundary layer control, structural adhesives for metal aircraft, thermal de-icing, aerodynamics of compressor blade vibration, power plants for helicopters and delta aircraft. The Conference is open to members of the Institute of the Aeronautical Sciences, and members of the Royal Aeronautical Society, 4 Hamilton Place, London, W.1, from which further particulars can be obtained.

Summer School of Physics

The Italian Physical Society, under the auspices of the Ministry of Education and the National Research Council, is organizing an international school of physics, to be held at the Villa Monastero, Varenna, Lake Como, during August 19–September 12 under the direction of Prof. Giampietro Puppi, professor of theoretical physics in the University of Bologna. The subject to be considered will be problems relating to the detection of elementary particles, with special reference to cosmic radiation, and the three individual topics and the respective lecturer will be as follows: the cloud-chamber method, Prof. P. M. S. Blackett (Imperial College of Science and Technology, London); nuclear emulsion method, Prof. C. F. Powell (University of Bristol); and primary cosmic radiation, Prof. H. Alfvén (Institute of Technology, Stockholm). All lectures and the accompanying seminars and discussions will be conducted in English or French. The school will be limited to 20–25 persons. The fee, including full board, will be 30,000–35,000 lire. Application forms should be sent before July 30 to Prof. G. Puppi, Società Italiana di Fisica, Via Saldini 50, Milan, Italy, from whom all further information can be obtained.

Lectures by Members of the Everest Expedition

The Royal Geographical Society and the Alpine Club, by arrangement with Wilfred Van Wyck, are organizing twelve illustrated lectures on "The Ascent of Everest", to be given at the Royal Festival Hall, London, S.E.1, on the evenings of September 15, 16, 18, 19, 21, 22, 23 and 28, October 13 and November 2, at 8 p.m., and on the afternoons of September 19 and October 10 at 3 p.m. The lectures will be by Colonel Sir John Hunt, leader of the Everest Expedition, Sir Edmund Hillary, A. Gregory, Major C. G. Wylie, W. G. Lowe, T. D. Bourdillon and C. W. F. Noyce. The proceeds from the lectures, and from those to be given in the provinces and abroad, will go to a trust fund for exploration in mountain regions. The first evening, September 15, will be a gala event, for which further details will be announced in due course. Tickets for the lectures (prices 15*s.*–3*s.* 6*d.*) will be on sale at the Royal Festival Hall and the usual agents as from July 27. Further information can be obtained from the Secretary of the Royal Geographical Society, 1 Kensington Gore, London, S.W.7.

The Night Sky in August

New moon occurs on August 9d. 16h. 10m., U.T., and full moon on August 24d. 20h. 21m. The following conjunctions with the moon take place: August 5d. 03h., Jupiter 4° S.; August 6d. 02h., Venus 5° S.; August 8d. 02h., Mercury 3° S.; August 15d. 11h., Saturn 8° N. In addition to these conjunctions with the moon, Mercury is in conjunction with Mars on August 23d. 14h. Mercury is too close to the sun to be seen during the early portion of the month, but towards the middle of the month it rises about 3h. 10m. and may be seen for a short time before sunrise, stellar magnitude 0·1; after this it approaches the sun and on August 31 rises only forty minutes before sunrise. Venus, a morning star, rises at 1h. 10m., 1h. 20m. and 1h. 50m. on August 1, 15 and 31, respectively; the visible portion of its illuminated disk varies between 0·67 and 0·78, and its stellar magnitude averages − 3·5. Mars rises at about 3h. 40m. throughout August and is not well placed for observation, as it is rather close to the sun, until the end of the month when it rises more than an hour and a half before the sun; about August 9 it lies nearly midway between δ and γ Cancris, but will not be easily seen at that time. Jupiter rises at 0h. 30m., 23h. 40m. and 22h. 50m. at the beginning, middle and end of the month, respectively, stellar magnitude about − 1·8; after the middle of the month it will be seen a little north of ζ Tauri, which it approaches during its slow easterly movement. Saturn sets at 22h. 15m., 21h. 20m. and 20h. 20m. on August 1, 15 and 31, respectively, and lies about midway between α and ζ Virginis and a little east of θ Virginis. A partial eclipse of the sun, greatest magnitude 0·372, occurs on August 9, but is invisible at Greenwich. The Perseid meteor shower attains a maximum during August 10–12. Only one star brighter than magnitude 6 is occulted during the month, 49 Sgtr. disappearing on August 21d. 23h. 02·8m.

Announcements

The College of Physicians of Philadelphia has awarded the Alvarenga Prize for 1953 to Dr. F. D. Moore, surgeon-in-chief in the Peter Bent Brigham Hospital and Mosely professor of surgery in Harvard Medical School, for his outstanding contributions to knowledge of the changes in body metabolism following surgery. The Alvarenga Prize is an annual award established in 1883 by the late DaCosta Alvarenga, of Lisbon, Portugal, an associate fellow of the College.

The following resignations have been announced from the University of Sheffield: Prof. E. J. Wayne, from the chair of pharmacology and therapeutics, on his appointment as regius professor in the practice of medicine in the University of Glasgow; and Dr. H. J. Cowan, lecturer in civil engineering, on his appointment to the chair of architectural science in the University of Sydney. Mr. J. F. Fleming has been appointed lecturer in civil engineering in the University.

The University of Padua is offering a Gabriella Zuccari scholarship of 300,000 lire for research of at least seven months duration at the Zoological Station, Naples, during 1954. The scholarship is open to any person who wishes to undertake research in zoology, comparative anatomy, physiology or embryology, and it may be renewed up to a maximum of three years. Application forms (to be returned by October 31) and further information can be obtained from the Secretariat of the University of Padua.

UTILIZATION OF RADIATION FROM FISSION PRODUCTS

A SYMPOSIUM on the use of fission-product radiation was held by the Chemistry Division at the Atomic Energy Research Establishment, Harwell, during February 23–24. Invited representatives of the chemical and pharmaceutical industries and of those interested in using radiation for food preservation and medical purposes attended the meetings in addition to members of Harwell and of the Radiochemical Centre, Amersham, and the Production Branch of the Directorate of Atomic Energy. The object of the symposium was to decide what steps should be taken now by the Directorate and by potential users if fission-product radiation is to be used fully in the national interest.

In his introduction, Dr. R. Spence (chief chemist at Harwell) said that we should expect by 1970 that the output of fission products could be of the order of one ton per year, representing 2×10^{10} MeV.-curies (equivalent to 120 MW.) from the fission-product radiation alone. Even if this energy were used with only 1 per cent efficiency, this represents a considerable power output for such a unique form of energy. Storage of this active material would represent a serious embarrassment to the atomic energy project, and use of the radiation energy from these by-products could reduce the cost of nuclear power.

The first part of the symposium was concerned with the nature of the fission-product sources and with ways of using the radiation energy. In a paper on the use of gamma radiation from reactor fuel rods, Dr. W. Wild and J. Wright (Harwell) discussed ways of storing fuel rods during their 'cooling' period (between irradiation and chemical processing) so that the emitted gamma radiation could be used. Without any interference with present operations, the 70 per cent of the total gamma radiation which is emitted during this period can be used to give dose-rates up to 10^4 r./min. A nuclear power station producing 240 MW. of electrical power would provide enough fission products to treat 2,000 tons of material per day with a dose of 10^6 r.

A paper by Dr. C. B. Amphlett (Harwell) dealt with the use of the radiation from fission-product wastes and showed that use of the beta energy from the solutions left after chemical processing depends upon fabrication of suitable irradiation vessels with thin partition walls. Calculations of the yield of chemical products obtainable with selected geometrical arrangements show that the most suitable radiation chemical processes for industrial use of fission-product energy would be chain reactions of high yield such as polymerizations, or reactions contributing to the synthesis of some expensive product required only in relatively small quantities. Reactions with yields of less than 10 molecules per 100 eV. of energy absorbed are unlikely to compete in output with orthodox chemical industry.

By separating active fission products from inactive material very high specific activity can be obtained so that self-absorption in the source is reduced to a minimum. The total production of many of the longer-lived fission products can be utilized efficiently throughout much of their life, leaving relatively inactive end-products. This was discussed by G. N. Walton (Harwell) in a paper on the specific activity of separated fission products from reactor fuels. Following the principle that the shorter the life of the fission product concerned, the less is the mass of material involved in the transfer of power, calculations were made of the power which would be carried by short-lived rare-gas fission products which might be removed direct from the reactor core and piped past the target material.

The separation of long-lived fission products was discussed by P. E. Carter (Amersham) by reference to the chemical processes and plant used for separation of several curies per year of strontium-90 and cæsium-137. The description of this plant, which may serve as a prototype for large-scale separation of these fission products, illustrated some of the problems which will be met in preparing large sources of high specific activity.

In discussing the value of these different types of fission-product source, it was emphasized that efficient utilization of the radiation requires these materials to be used continuously as they are produced and at all stages of their decay. The removal of short-lived fission products during operation of the reactor would involve modifications to the design of the latter but might lead to improved performance, since some of the fission products are nuclear 'poisons'. The time during which fuel rods could be used as gamma sources might be reduced in future irradiation and 'cooling' schedules; but the use of fuel enriched in the fissile component would lead to higher specific activities after irradiation and would reduce self-absorption of radiation in the source. Use of the fuel rods or of the waste solutions at the concentration at which they would normally be stored would involve only the construction of suitable irradiation vessels.

There seemed no doubt of the technical feasibility of producing sources of megacurie activity which would be required for most large-scale uses of fission-product radiation; but it was emphasized that the initial capital cost would be very great. The present chemical-separation plant is designed to treat fission products as an objectionable by-product; modifications to enable their radiation energy to be used would be more costly than incorporation of these requirements in new plant. The cost of plant for handling active materials is, in any event, greater than that of ordinary chemical plant, not only because of the protection problems involved but also because of the difficulty of maintenance. This imposes severe restrictions on the methods and materials used for what are normally quite simple operations. The cost of concentrating waste solutions beyond the level at which they would normally be stored and the cost of separating individual fission products will be considerable and must be shared between the atomic energy project and the user of the source in accordance with the advantages derived by each.

The second session of the symposium, with Dr. W. Wild (Harwell) as chairman, was devoted to consideration of the uses of fission-product radiation in the chemical, pharmaceutical and food industries. M. W. Perrin (Wellcome Foundation, Ltd.), in a paper on the technical feasibility of the use of fission products, said that many of the radiation sources will be available only at the reactor sites or at the site of the chemical separation plant. This may contribute to the general re-location of industry both within Great Britain and between countries, this being, in any event, a likely consequence of the development of nuclear power. It is not yet known what radiation chemical reactions are likely to be of value in the industrial field, and the main need at present is for an extended survey of the chemical effects of radiation. It would greatly assist industrial research laboratories in studying systems of special commercial interest to them if they could draw upon men who had been taught the basic facts of radiation chemistry in the course of their university career. As an example of work of special commercial interest, L. Seed (Alkali Division, Imperial Chemical Industries, Ltd.) described some experiments in which an increase in rate of polymerization of ethylene was observed in the presence of gamma radiation from cobalt. Even with a source of only ¼ curie, the presence of a gamma-induced reaction could be detected by subtracting the value for the 'thermal' reaction.

Dr. J. W. Barrett, B. L. Budd, Dr. R. Roberts and Dr. D. S. P. Roebuck (Monsanto Chemicals, Ltd.) presented a paper on the economic feasibility of the use of fission products, which showed how the economics of a medium-sized chemical plant are worked out and the influence upon these figures of the cost of radiation sources. Until more technical data are available on radiation chemical reactions, yields and rates, it will not be possible to assess the economic advantages of using radiation. A profitable radiation-induced reaction should be sought among those processes for which capital expenditure and process costs are more important than the cost of raw materials.

In a paper on the preservation of food, Dr. R. S. Hannan (Low Temperature Research Station, Cambridge) summarized the present position of research into the use of ionizing radiations for sterilizing food. It has been established that doses of the order of 2×10^6 r. are necessary, and efforts are now being directed to eliminate the deleterious taste and odour which often result from this method of sterilization. The full techniques finally developed may prove too complex for economic application, except for very special products; but if the process does prove practicable on a wider range of common foodstuffs, many megacurie sources will eventually be required.

W. Jones (Imperial Chemical (Pharmaceuticals), Ltd.) read a paper on the sterilization of pharmaceutical products, which compared present methods of attaining sterility with what is known about the use of radiation for this purpose. While there is a place in the industry for an improved sterilization process, most large manufacturers are already equipped to operate older methods, and a suitable process for small manufacturers must be of low initial cost and economic in use. The advantages of using fission-product radiation—low maintenance cost and ability to sterilize the product in its final container—may ultimately prevail, but much more work is still required.

The last two papers in this session dealt with the effect of ionizing radiation on the physical properties and molecular structure of pre-formed plastics and of synthetic and natural high polymers. Speaking on high-energy radiation and long-chain polymers, Dr. A. Charlesby (Harwell) dealt with the physical changes in such substances as polythene, rubber, polystyrene and 'Perspex' subjected to pile radiation. The observed effects were interpreted in terms of cross-linking between polymer chains and other structural changes. Dr. K. Little (Harwell), in a paper on the effects of ionizing radiation on organic high polymers, attributed the observed changes to many chemical effects, of which cross-linking is only one. Experimental evidence for these conclusions was derived from examination of many fibres ('Orlon', nylon, silk, viscose, etc.) which had been irradiated in the pile.

In the course of the discussion it became clear that there is not sufficient information in either the technical or economic sphere to assess the potentialities of using fission-product radiation in the chemical industry. University research departments could help a great deal by building up a systematic chemistry of radiation effects. The economic assessment awaits more realistic estimates of the cost of producing sources of high specific activity. The type of source required, the site at which it is to be used, the design of irradiation vessel and many other factors are all dependent on the processes to be worked. Guidance on these points is needed at an early stage if full advantage is to be taken of the radiation energy as soon as it becomes available.

Technical feasibility in the preservation of food and sterilization of pharmaceutical products is less in doubt, and some idea of the required doses is already available. With materials for human consumption, however, many very important safety aspects arise. Most of the gamma-rays from fission products are of too low an energy to give appreciable activity through the neutrons produced by (γ,n) processes; but this aspect must be checked, especially for the short-lived fission products. It must also be established beyond reasonable doubt that toxic compounds, including carcinogens, are not produced in irradiated material and that consumption of that material on a large scale and over long periods will have no harmful effects. These are formidable obstacles; but the potential value of the method is great.

In regard to the medical aspects of the subject, it was emphasized that the handling and utilization of megacurie sources would be intrinsically very dangerous, and an important part of the energy and cost of development of the new methods must be applied to these protection problems.

The third session dealt with separated fission products, for many of which important uses have already been found, and this session was therefore less speculative in nature than the earlier ones. Prof. W. V. Mayneord (Royal Cancer Hospital, London), who presided at this session, outlined some of the medical uses of radiation, pointing out that the overall amounts of material required for these purposes are likely to be very much less than the total production; kilocuries of some isotopes, such as cæsium-137, would, however, be required.

Dr. W. P. Grove (Amersham) described methods of mounting separated fission products safely for industrial and medical use. By forging active oxides or salts into silver or other metals, thin foils or plaques can be obtained in which the beta activity suffers little self-absorption and from which no active contamination is removed by rubbing, boiling in water, or similar treatment.

In a paper on cæsium-137 and its use, W. S. Eastwood (Harwell) pointed out that this isotope has a very long-lived beta-gamma emission which is likely to be valuable in medicine for radiotherapy.

Sources of about 5,000 curies mounted in a 5-cm. cube could be used in place of an X-ray teletherapy unit and, unlike the latter, could not fail at a critical moment. Such cæsium-137 sources would also be ideal for use by industry in research and development on radiation chemistry. Dr. J. W. Arrol (Harwell) described the handling and uses of some other fission products. Iodine-131 is used extensively in medicine, and the plant for its large-scale production from fission products was described. The rare gas, krypton-85, is particularly valuable because of its chemical inertness and its radioactive long life. The fact that it is almost a pure beta-emitter makes it possible to handle very high activity sources with little shielding. Its use as a static eliminator, in ventilation control, and for sterilization of blood plasma was suggested.

As a result of this symposium it became clear that the following steps should be taken if the full and efficient use of the radiation from fission products is to be ensured in Great Britain. The assistance of university research departments should be enlisted in an effort to build up gradually a systematic chemistry of radiation effects, particularly in mixtures of organic substances. Industrial research laboratories should be encouraged to use the sources now becoming available to carry out short-term studies of radiation effects which may be of special interest to them. The technical problems of preventing unpleasant taste and odour and of ensuring safety of the product clearly require further attention in the field of food preservation and pharmaceutical sterilization. Realistic estimates of the cost of making available large fission-product sources from existing and from future plant should be prepared. Plans already made for the production of sources of high specific activity from fission-product wastes should be implemented, since this will not only provide sources for medical and industrial use but will also furnish the basic information needed for technical and economic estimates of future large-scale production of sources.

As information becomes available from this work, the overall advantages of using fission-product radiation must be assessed on a national basis and, by close collaboration between the atomic energy project and potential users, a scheme should be worked out for apportioning the additional cost of providing the facilities.

The papers presented at this symposium, together with a full account of the discussion, are being prepared as a Harwell report, and will be on sale at Her Majesty's Stationery Office. The present account is published by permission of the Director of the Atomic Energy Research Establishment.

SOLUTIONS OF ELECTROLYTES IN ORGANIC SOLVENTS

A SYMPOSIUM on "Solutions of Electrolytes in Organic Solvents" was held at Buckland House, Buckland, Berks, on April 15 by invitation of the Physical Chemistry Group of the Atomic Energy Research Establishment, Harwell. About fifty people attended, including visitors from various universities and institutions in the United Kingdom and overseas. The meeting was under the chairmanship of Dr. E. Glueckauf (Harwell), who, in his opening remarks, said that the nine papers to be discussed were grouped into three sections: solvent extraction and the nature of addition complexes; acid-base phenomena in non-aqueous solutions; and the constitution of solutions containing iodine.

The first paper, by T. V. Healy and Dr. G. M. Waind (Harwell), was on "The Extraction of Metal Nitrates into Phosphate Esters". Mr. Healy discussed the differences in the extraction of cobalt, sodium, and uranyl nitrates from aqueous solutions by tributyl phosphate, and also partition data for uranyl nitrate between water and the solvents dibutylphenyl phosphate, diphenylbutyl phosphate and triphenyl phosphate. He showed that the thermodynamic equilibrium constants and free energies of transfer of uranyl nitrate between the various solvents are in the order expected from the electron-donor properties of the solvents. Deviations from ideality above $0 \cdot 1\,M$ were used for estimating approximate solvation numbers for the complexes (for example, $n = 2$ for $UO_2(NO_3)_2.n(BuO)_3PO$). More accurate values were obtained from partition data (with organic concentrations $< 0 \cdot 1\,M$) in the presence of inert diluents, in conjunction with solvent activities obtained from vapour-pressure measurements.

Dr. H. M. Feder (Argonne National Laboratory, Chicago), in a paper entitled "The Stability of Molecular Addition Compounds: a Solubility Technique", dealt with the formation of compounds between mercuric chloride and various alcohols and carbonyl compounds in carbon tetrachloride. Although equilibrium was reached more slowly in organic media than in aqueous solutions, the results were reproducible, and enthalpy, free energy and entropy changes for the reactions were evaluated with good precision. After discussing the applicability and limitations of the solubility technique, Dr. Feder presented results on uranyl nitrate dihydrate with a wide variety of organic bases (donors). Formation constants thus obtained were compared in terms of the general Lewis acid – base theory, as modified by steric requirements.

The discussion on these two papers was opened by Prof. W. F. K. Wynne-Jones (Newcastle upon Tyne), who criticized the use of the term 'base strength' when applied to Lewis donor species. He pointed out that the term can be precisely and usefully defined in the conventional way in aqueous systems, and showed that an attempt to generalize this to obtain a sequence of base strengths valid for all systems merely results in a confused state where a unique order is not even defined within the one solvent. This was supported by Prof. J. A. A. Ketelaar (Amsterdam). In answer to R. P. Bell (Oxford), Mr. Healy said that the water content and electrical conductivity of sodium nitrate solutions in phosphate esters have not yet been determined.

In the session before luncheon, two papers were read from the Atomic Energy Research Establishment, Harwell. H. A. C. McKay, who spoke on "The Partition of Nitric Acid between Water and Ethers", considered first the binary water – ether systems. The differential heats of mixing indicate compound formation, and the water-vapour pressure curve in the water – pentaether system indicates interaction between the dissolved water molecules in the pentaether. In polyethers, the oxygen atoms appear to act independently of each other when forming complexes with water or uranyl nitrate. Mr. McKay said that conductivity and viscosity measurements show that, in most cases, the nitric acid may be considered as un-ionized in the ether phase, so far as partition results are concerned. The amount of water accompanying the nitric acid into the organic phase varies considerably from ether to ether. The paper concluded with a discussion of the plots of nitric acid activity against the mole ratio of nitric acid to ether, which are strictly linear only at the lowest concentrations.

Dr. Glueckauf's paper on "The Ternary System Nitric Acid – Water – *n*-Butyl Ether" was a thermodynamic analysis based on partition experiments (activities), phase composition data, and molal heat contents obtained by Miss B. L. Ford (Harwell). The four characteristic features of the system are: complex formation, with hydrogen bonding, of butyl ether and nitric acid in 1 : 1 ratio ($-\Delta H =$ 7 kcal./mole); association of this complex with water; partial formation of a bimolecular species

$$(Bu_2O.HNO_3)_2.xH_2O\ (x < 1),$$

as indicated by the trend of activities; absorption of nitric acid as a species in which the 1 : 1 ratio is exceeded, in those solutions where the mole ratio of nitric acid to ether approaches unity. This species has a much higher heat content ($\Delta H \simeq 3$ kcal./mole nitric acid) than the normal 1 : 1 complex; and the trends of activities and heat contents are consistent with bimolecular association. Dr. Glueckauf said that these four types of interaction are typical of the ternary systems of all ethers in equilibrium with aqueous nitric acid solutions.

In the discussion, Prof. Wynne-Jones directed attention to the difficulty of obtaining precise formulæ for the addition complexes from purely thermodynamic arguments, and Dr. Feder suggested that, with so many simultaneous equilibria, progress in the detailed understanding of such a ternary system by this method might be rather slow. Mr. Bell and Prof. Ketelaar alluded to the possibility of identifying the complexes postulated by ultra-violet absorption spectroscopy. Dr. Glueckauf replied that two-phase equilibration, using solutions of known activity, permits observations over a greater range than can be attained by almost any other method, and he recommended its wider application, preferably in combination with other techniques.

The first speaker in the afternoon was Prof. Wynne-Jones, who contributed a paper on "The Interaction of Acids and Bases in Non-Aqueous Solvents". After a brief historical survey which stressed the influence of hydrogen bonding in reducing the degree of ionization in non-aqueous systems, he pointed out that such bonding may result in both a displacement of the absorption bands and also a marked entropy change. This was illustrated by results on the interaction between a number of amines and nitrophenols in benzene solutions. By measuring the absorption for different acid/base ratios at a series of temperatures, full thermodynamic data were obtained for the equilibria. The strikingly large entropy effects (~ 30 cal. deg.$^{-1}$ mole^{-1}) were explained by assuming that the benzene molecules are powerfully oriented by the strongly polar compounds. Prof. Wynne-Jones related these results to the mechanism of the Menschutkin reaction and concluded by observing that, in such solvents, the concepts of acid and base tend to lose their sharpness of definition.

Dr. D. D. Eley (Bristol) then presented a paper on "Solutions of Aluminium Halides" which discussed recent results obtained in collaboration with Dr. P. J. King (Bristol). Whereas aluminium bromide gives an ideal solution of Al_2Br_6 molecules in benzene, addition of hydrogen bromide results in the formation of two liquid phases. The upper phase has a low electrical conductivity; but the lower phase, of composition $Al_2Br_6.HBr.6C_6H_6$, is highly ionized. Before addition of hydrogen bromide, the solution has an absorption band at 2785 A. due to $Al_2Br_6.nC_6H_6$; this may be attributed to a charge-transfer spectrum. The introduction of hydrogen bromide suppresses this band, and a new absorption appears at 3300 A. which eventually spreads to 5500 A. at high concentrations. Dr. Eley said that an increase in the pressure of hydrogen bromide, while effecting relatively little variation in the composition of the individual phases, caused the lower to grow at the expense of the upper.

There was a lively discussion of both these papers. Prof. R. S. Mulliken (Chicago), Dr. F. Fairbrother (Manchester) and Dr. N. N. Greenwood (Harwell) spoke of the possible structure of the molecular addition compounds and of the relation of Dr. Eley's results to those in systems containing aluminium chloride and boron trifluoride. Dr. A. R. Mathieson (Nottingham) reported some observations on the effect of aluminium chloride on the spectrum of benzene in *n*-hexane solution: whereas the benzene bands between 2400 and 2650 A. are unaffected, aluminium chloride enhances the absorption below 2400 A. This absorption does not obey Beer's law and suggests formation of a complex. Dr. Mathieson also pointed out that the single peak at 2820 A., obtained for a solution of aluminium chloride in pure benzene, is similar to that observed for a solution of aluminium bromide in the same solvent.

The last group of papers dealt with solutions containing iodine. Dr. L. I. Katzin (Argonne National Laboratory, Chicago) spoke on "Solvation Effects in the Tri-iodide Equilibrium". He first considered the general effects of dielectric constant, donor strength, and stoichiometry on solvation, and then discussed some results obtained with aqueous *t*-butyl alcohol solutions of *t*-butylammonium iodide or sodium iodide, in the presence of iodine. The tri-iodide dissociation constants were obtained by a spectrophotometric dilution technique, using the absorption peak at 3550 A. This gave, independently, both the dissociation constant and the extinction coefficient. Dr. Katzin showed that the shape of the curves of optical density against water content for sodium tri-iodide can be ascribed to a cation hydration effect which is largely complete at low water concentrations. The significance of these results for theories on the constitution of iodine solutions was outlined.

Prof. Ketelaar followed with a paper on "The Colour and Constitution of Iodine Solutions". He pointed out that specific solvation of iodine in solvents such as the chlorinated olefins, though well established, is yet so weak as to leave unaffected the visible absorption spectrum. In the ultra-violet, however, absorption due to the complexes formed is observed. Prof. Ketelaar said that, in a group of related compounds, there is a linear correlation between both the free energy and heat of formation, on one hand, and the frequency of absorption and ionization potential of the donor, on the other. Using benzene as an example, he calculated the difference in bonding energy between the two configurations of the resonance-complex, and showed that this decreases with increasing methyl substitution.

Dr. Greenwood presented the final paper of the symposium, dealing with "The Electrical Conductivity and Colour of Iodine Solutions". Experiments were described which correlated the colour, conductivity and chemical reactivity of solutions containing iodine, bromine, iodine monochloride or iodine monobromide. He showed that, whereas all violet solutions of iodine are non-conducting, brown solutions conduct ionically by virtue of the equilibrium :

$$\text{solvent} + 2I_2 \rightleftharpoons \text{solvent } I^+ + I_3^-.$$

When a donor solvent is added to a violet solution, it turns brown with simultaneous onset of conductivity. Again, the effect of heat, in tending to alter brown solutions reversibly to violet, is paralleled by a decrease in conductivity which increases again on cooling. Dr. Greenwood pointed out that ionic reactions typical of either the iodine cation or the tri-iodide anion occur rapidly in brown solutions but not in violet solutions, and that there are important similarities between the ultra-violet spectra of brown solutions and the spectrum of the tri-iodide ion.

Prof. Mulliken opened the discussion of these papers by considering in detail the nature of the iodine complexes and their relation to charge-transfer spectra. The structure of the tri-iodide ion was also discussed. Mr. Bell described experiments designed to measure the concentration of positive iodine in strongly acid solutions, and contributions were also made by Dr. Fairbrother and Prof. Wynne-Jones on the significance of dipole measurements in solutions containing iodine and the use of spectrophotometric techniques to obtain equilibrium constants in solution.

The symposium concluded with a short summary of the day's proceedings by Prof. Wynne-Jones. Informal discussions were continued after dinner and provided a fitting sequel to a pleasant day at Buckland House.

N. N. Greenwood

SOUTH-WESTERN NATURALISTS' UNION

CONFERENCE AT ILFRACOMBE

The South-Western Naturalists' Union held its twenty-sixth annual Whitsuntide Conference at Ilfracombe during May 22–25, at the invitation of the Ilfracombe Field Club. The meeting opened with a reception on May 22, when the chairman of the Ilfracombe Urban District Council, Mr. H. P. Smith, welcomed the members; afterwards, Mr. E. Gill showed a series of films illustrating marine and terrestrial life.

On May 23, the general annual meeting of the Union was held, the chair being taken by the president of the Union, Mr. Mervyn G. Palmer. In his report the honorary secretary, Dr. Stanley Smith, stated at the present time the Union embraces twenty natural history societies, one institution and one private member; since the last general meeting, held at Plymouth on June 2, 1952, the Salisbury and District Naturalists' Field Club has become affiliated. He announced that three of the affiliated societies, together with a fourth body, have acquired the tenancy of Steep Holm in order to preserve its natural amenities and to make these available to naturalists. Particulars concerning the conditions under which permission to visit the island are granted can be obtained from Mr. J. H. Savory, 61 Lower Redland Road, Bristol 6. Dr. Smith also directed the attention of the Union to the lamentable destruction of the Long Barrow near Marlborough, Wiltshire. A resolution was passed expressing the Union's concern at the loss of these ancient monuments. A letter from the secretary of the Bristol Naturalists' Society, Mr. C. S. Carlile, inviting the Union to hold its next conference at Bristol was read, and this invitation was unanimously accepted.

The election of officers for 1954 concluded the proceedings. Mr. E. R. Harris (Plymouth) was elected president; and the honorary secretary, Dr. Stanley Smith, the honorary treasurer, Mr. H. W. Turner, and the honorary auditor, Dr. F. S. Wallis, were asked to remain in office. Mr. C. S. Carlile and Mr. R. W. Hall were added to the Council.

In the afternoon, members visited Arlington Court, which for many generations had been the home of the Chichester family and is now the property of the National Trust. In the evening, a lecture on "High Lights and Shadows of Bird Photography" was given by Mr. E. H. Ware.

A comprehensive tour of north-west Devonshire occupied the whole of May 24. On the outward journey St. Nectan's Church, Stoke, was visited and the contorted strata at Hartland Quay were examined. At Hartland Abbey the party was met by Major Stuckley, the owner, and was conducted by him over the house, which is of considerable architectural interest and contains many treasures. On the property is one of the few remaining breeding grounds of the large blue butterfly (*Maculinea arion* (Linn.)). Major Stuckley explained that the area has been fenced around, in an endeavour to preserve the insect, the remarkable life-history of which he briefly outlined. Members were shown over Clovelly Dykes (earth-works attributed by Lady Fox to Iron Age *B*) by Mr. J. C. and Mrs. Hilton. Mr. Hilton also showed flint arrow-heads and other stone implements found in the neighbourhood. He explained that the flint-working site was within a quarter of a mile of the Dykes.

There was a short excursion on the morning of May 25 to Chapel Wood Bird Sanctuary, Spreacombe, owned by the Royal Society for the Protection of Birds and under the administration of the Ilfracombe Field Club.

NATIONALIZED INDUSTRIES IN GREAT BRITAIN

RELATIONS WITH THE PUBLIC

The Acton Society Trust has published a number of studies surveying certain aspects of the nationalized industries that appear to be specially important, and the last of these studies, No. 12, deals with the relations which are being developed between the nationalized industries[*]. It is a subject of crucial importance, and, although some parts of it have been discussed in earlier studies, this brief account of the arrangements so far made to foster relations with the public bears closely on the three main topics to which the previous studies have been devoted. A satisfactory solution of this problem would go far to resolve that of the accountability of the industries to Parliament or of their internal industrial relations, and might even contribute substantially to remove some of the difficulties noted in the distribution of authority and the supply of those qualified to wield authority.

---

[*] Acton Society Trust. Nationalized Industry Series 12: Relations with the Public. Pp. 39. (From the Trust, 39 Welbeck Street, London, W.1. 1953.) 2s.

The first impression derived from this study is that of the confusion which arises from lack of clear thinking and the failure to reconcile in practice the different interests which nationalization was intended to serve. Next it is clear that some aspects of the conduct of these vast industries go unstudied and unnoticed, and it is possible that much of what the public really thinks and wants is overlooked. A public relations service is clearly essential, and the question is what form it should take.

The study points out that success in this field depends above all on the attitude of the Boards: if their members are insensitive to the problem, the public relations officers can do little, nor has any agreement been reached within the industries on the functions of a public relations department. Few public relations officers appear to have a clear conception of the limits of their obligations, and the Trust suggests that the position of such departments in the nationalized industries requires review in terms both of the functions assigned to them and of the qualifications of their staffs. Moreover, the role of Parliament in this field is limited, and, although the present handicap on its effectiveness may diminish with time, the present system of parliamentary accountability has a strong decentralizing influence which so far the system of consumer councils has failed to counteract. While there is scope for detailed inquiries by universities, research institutions and other interested bodies, which could keep the public in close touch with the performance of the industries, such independent inquiries would have to be conducted on a systematic and intensive basis.

The Trust concludes from this study that the nationalized industries need to give far more attention to this problem, and, in particular, to take a much wider view of their responsibilities than the duties imposed by the nationalizing Acts. They need to find out far more than they already know about the consumer and his views, and the Trust cites the listener research of the British Broadcasting Corporation as an example of what might be done, possibly in co-operation with the consumer councils. No gentler hint that some industries—the study disclaims any inclusive validity for its conclusions—need to become more mindful of the idea of public service could well be given, but the main emphasis is on the flow of information in both directions—from, as well as to, the Boards. The final conclusion, however, is the most urgent: the centre of interest in the relations of the industries with the public needs shifting away from the top. The spur of public scrutiny must be applied at all points, for without ultimate control by Parliament domination by the sectional interests, already so much in evidence, may well follow; but for the individual consumer the basis of public relations is local. The industries should turn their attention to this in an attempt to overcome the feeling of remoteness which many of the public undoubtedly feel and which, as Mr. L. Hardern pointed out last year in his contribution on this theme to "Problems of Nationalised Industry", provides "all the elements of a growing opposition or hostility to the whole of the nationalised industries, irrespective of the success or efficiency they may achieve in their tasks". Apart from quoting that passage from Mr. Hardern's paper, the Acton Society Trust makes little reference to this factor of public confidence and goodwill or to the handicap which the growth of suspicion and misunderstanding could prove to the nationalized industries. Mr. Hardern's paper makes the more useful complement to that of the Acton Society Trust because it includes constructive suggestions for improving the public relations service so as to promote mutual respect and co-operation in the continuous improvement of efficiency and standards of service and morale.

ECONOMIC POSITION OF CAMEROON WOMEN

A RESEARCH grant from the Colonial Social Science Research Council enabled Dr. Phyllis M. Kaberry to study the economic position of women in the Bamenda division of the British Cameroons during the years 1944 and 1948, and she is to be congratulated on having published some of the results of her researches so expeditiously and in such detail[*]. This 220-page paper-backed report (which is rather high in price) gives a very clear account of the role of women in this very pleasant and atypical region of West Africa—a high grassy plateau, well watered and fertile with as yet no problems of erosion or over-population; it is a region which, through no fault of its own, was split between the British and French mandated areas after the First World War.

The serious part of this report is, no doubt, contained in the chapters on standards of living and on Kumbaw budgets, eighteen of which are given in full in an appendix; but the average reader will probably prefer the more general chapters on the way these people live, and on the things in life which they value. In Bamenda they consider that it is the man's job to rule and to provide the very modest cash income of the household, and it is the woman's to grow the food and to feed the family.

The Nigerian Government, to judge from Prof. C. D. Forde's preface to the report, considers the status of women in Bamenda to be unduly low and to constitute one of the contributory causes of the under-population of the region as well as a social obstacle to its economic development. Dr. Kaberry's report leaves one with the impression that this status, even if it might be considered low by comparison with urban Yoruba and with certain Ibo and Ibibio groups in the eastern region of Nigeria, is certainly not a contributory cause of under-population. If a comparison could have been made with other parts of the Cameroons or even with some of the adjacent 'pagan' provinces of the northern region, quite different opinions might have been formed. It is, after all, only by a political accident that the British Cameroons has become a province of the eastern region, a region which differs completely from Bamenda ecologically, economically and culturally. As for being an obstacle to development, this surely depends primarily on how the women are approached. Any plans for economic development, as Dr. Kaberry says, must take into account the fact that women will continue to assume the major responsibility for agriculture; the immediate problem, therefore, is to improve their techniques and their organization of labour. The present policy of demonstration plots and "instruction in needlework and hygiene" is unlikely to make much impression upon them.

EFFECTS OF SALTS ON INTERACTIONS IN POLYELECTROLYTE SOLUTIONS

By Prof. J. A. V. BUTLER and Dr. B. E. CONWAY

Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, London, S.W.3

In recent years a number of investigations has been made in capillary tube viscometers of the viscosity of aqueous solutions of polyelectrolytes and the effect of added salts thereon. The effects have been interpreted in terms of the theory of polyelectrolyte molecules by Arnold and Overbeek[1], and by Fuoss[2]. According to this theory, the effect of salts is to cause a coiling of the polyelectrolyte chain owing to a decrease of the repulsive forces of its charges.

In the case of deoxyribonucleate solutions, similar effects might be expected *a priori*. A large decrease of the viscosity is brought about by salts at moderate concentrations (10^{-3}–10^{-4} gm./ml.), but at extremely small concentrations an entirely different type of behaviour has been observed. Pouyet[3] found in a study of the viscosity of such solutions in the Couette viscometer that the reduced viscosity (η_{sp}/c) decreases rapidly with diminishing concentrations in the region between $c = 10^{-4}$ and 10^{-5} gm./ml., and in the limit $c \rightarrow 0$ approaches the same limiting value as the (constant) value which it has in salt solutions. This type of behaviour has been confirmed by us[4] with several samples of deoxyribonucleic acid, which differ somewhat in the concentration at which the decrease of viscosity begins. Also, very small concentrations of salts (10^{-5}–10^{-4} *M*) have a marked effect on the viscosity at concentrations above those which possess the limiting value[4].

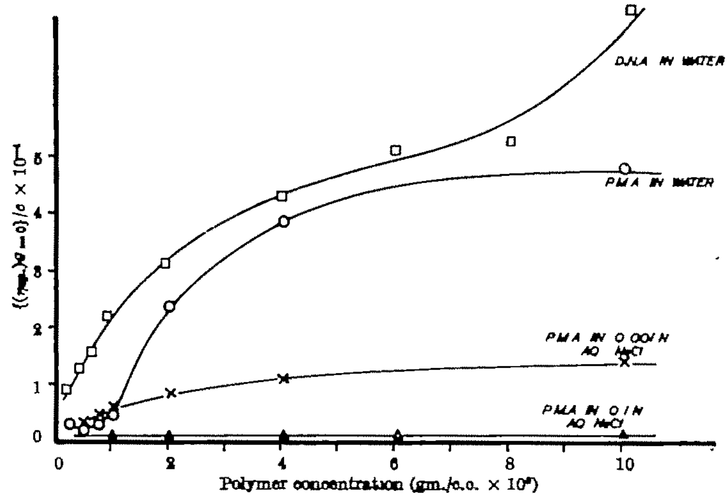
A falling off of the reduced viscosity of polymers at very small concentrations was observed by Boyer and Streeter[5] and by Moore and Russell[6], who attributed it in part to adsorption from the very dilute solutions on the surfaces of the viscometer. This does not seem to be a significant factor in our experiments, as the solution was poured out of the viscometer and replaced until a constant value of the viscosity was obtained. A maximum of the specific viscosity of polymethacrylate solutions at $c = 0{\cdot}05$ per cent was observed by Alexander and Hitch[7].

It therefore seemed to be interesting to determine the effect of salts on specific viscosities of solutions of a typical polyelectrolyte, at smaller concentrations than any yet recorded and at very low shear rates, to see if a similar type of behaviour occurs. We have made such measurements in the Couette apparatus with a highly polymerized polymethacrylic acid of molecular weight $2{\cdot}2 \times 10^6$ (used as 60 per cent sodium salt) kindly given us by Dr. P. Alexander, and the results are given in the accompanying graph. As can be seen, the behaviour is very similar to that of deoxyribonucleic acid. However, it has been difficult to reach sufficiently low concentrations to establish with certainty whether the intrinsic viscosity of this material reaches the same value in water as in salt solutions; but there is no doubt that the effect of salts (in the limit of zero shear), which is very great at moderate concentrations, is greatly diminished at concentrations of the order of 10^{-5} gm./ml.

At concentrations below those where the rapid fall of η_{sp}/c occurs, namely, 0·003–0·001 per cent, it is noticeable that the plot of η_{sp}/c is again nearly horizontal. This may indicate that a region is now being approached where the particles are moving independently and intermolecular interaction is no longer significant. This behaviour between 0·001 and 0·00025 per cent also confirms that adsorption effects are not vitiating the results.

The interpretation of these facts would be difficult except on the same basis as already suggested in the case of solutions of deoxyribonucleic acid, namely: (1) that increase of reduced viscosity with concentration is due to increasing interaction of the particles, and (2) the extent of the interaction at a given concentration is greatly reduced by even a small concentration of salts. Hence, the interaction of the polyelectrolyte particles must be regarded as a general feature in all but the most dilute solutions; and the effect of salts on the viscosity should not be ascribed solely to changes of extension of the particle. Incidentally, it might be noted that the reduction of viscosity by 0·1 *N* sodium chloride on 10^{-4} gm./ml. polymethacrylate is of the order of 99·5 per cent. On the basis of the present measurements, it is impossible to exclude a relatively small effect of the salt on the intrinsic viscosity (*c.* 50 per cent), so that some change of shape of the isolated particle may occur in the presence of salts. But it would be difficult to explain the increase of the reduced viscosity with concentration, except on the basis of interaction.

If this view is correct, we may inquire into the origin of interactions of polyelectrolyte particles which occur at low concentrations and are greatly reduced by even small concentrations of salts. It has been suggested[7] that hydrogen bonding occurs and is responsible for the abnormal dependence on shear in such solutions; but it is difficult to see how hydrogen bonds could be sensitive to small amounts of salt. We find it difficult to avoid the conclusion that the interaction must be electrical in nature and due to interionic forces between the polyions and their



Reduced viscosities η_{sp}/c of dilute solutions of: (1) deoxyribonucleic acid (DNA) in water; (2) polymethacrylate (PMA) in water and salt solutions counter ions. The counter ions may, in fact, attempt to complete their ionic atmospheres by attracting more than one polyion, and this will give rise to attractive forces between the polyions—an effect which would be greatly diminished by added salts. An effect of this nature was proposed by Staudinger[8] in his 'swarm' theory, but it has been held that the facts support a 'shape' theory better[9]. Also Overbeek and Verwey[10] have found theoretically that the double layers of two (large) charged particles tend to repel each other. The interaction of charged rod-like particles has also been studied by Dube[11], whose calculations suggest that an attractive force between particles may occur under certain conditions. It could be argued that the decrease of interaction produced by salts is a consequence of a change of shape or configuration, but this does not agree with the comparatively small effect of salt at small concentrations of polyelectrolyte and does not explain the nature of the interaction. A more extensive study of a variety of systems will be required before this can be confidently decided. The facts given above provide a new outlook on the problem and suggest that a considerable degree of electrical interaction arising from the interionic forces between polyions and their counter ions may be a common feature of such solutions, and that the abnormal dependence on shear of the viscosity of these solutions may be a consequence of such electrical interactions. The degree of interaction between two particles will vary continuously and will depend on their distance from a common ion. On this view, all degrees of interaction may be expected to occur and the shearing forces will themselves affect the amount of interaction since they will pull apart particles in which the electrical attraction holding them together is less than the force produced by the shear. A more detailed study of such effects is being made and will be published elsewhere.

We wish to thank Dr. P. Alexander for specimens of polymethacrylate. This investigation has been supported by grants to the Royal Cancer Hospital and Chester Beatty Research Institute from the British Empire Cancer Campaign, the Jane Coffin Childs Memorial Fund for Medical Research, the Anne Fuller Fund, and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service. [April 7.

Note added in proof (July 1). It is necessary to mention two possible alternative explanations of the effect observed. (1) At high dilutions hydrolysis of the polyelectrolyte salt might occur, resulting in a displacement of the equilibrium $NaP + H_2O \rightleftharpoons HP + NaOH$ to the right, so that at high dilutions a greater fraction of the polymer is present in the less viscous acid form. The ratio NaP/HP should depend on the pH of the solution, but measurements of this made in dilute solution show no significant change. (2) Since solutions exposed to air contain dissolved carbon dioxide, the reaction $H_2CO_3 + NaP = NaHCO_3 + HP$ will occur to a significant extent at high dilutions of the polymer, since the pK's of the two acids are of a similar magnitude. It is difficult to make the viscosity measurements in the Couette apparatus in the complete absence of carbon dioxide, but experiments with solutions which were free from carbon dioxide when prepared and measured as quickly as possible showed a marked decrease of the reduced viscosity on dilution. Although there was a slow decrease of these values with time on exposure to air, the initial values obtained should refer to carbon dioxide-free solutions. The observed decrease of viscosity on dilution therefore appears not to be due to the reactions mentioned.

STATISTICAL SIGNIFICANCE IN PSYCHICAL RESEARCH

By G. SPENCER BROWN

Department of Zoology and Comparative Anatomy, Oxford

IT is proposed to show that the logical form of the data derived from experiments in psychical research which depend upon statistical tests is such as to provide little evidence for telepathy, clairvoyance, precognition, psychokinesis, etc., but to give some grounds for questioning the practical validity of the test of significance used.

The recent aim of research workers setting out to demonstrate the occurrence of telepathy, etc., has been to devise experiments to give statistically significant results which might reasonably be interpreted as evidence for the phenomena claimed. They have succeeded in doing this, but with important limitations. In the first place, although some of the experimental results appear by statistical reasoning 'highly significant', identical experimental conditions do not as a rule bring about their repetition. Thus, in an important sense, the phenomena remain undemonstrated.

The other serious limitation in the so-called demonstrations of telepathy, etc., is the lack of satisfactory control series. This is because control series in this work cannot be relied upon to give results which are any the less curious and 'significant' than those of the main series. The classic example is Coover's[1] experiment in card guessing, where half the cards to be guessed by the subjects were known to the experimenter at the time of guessing, and the other half—the control series—were not known to anyone until afterwards. Coover found no appreciable difference between the results of the main series and those of the control, and rightly concluded that he had found no evidence for telepathy. It has since been pointed out[2] that both Coover's main series and his control show a deviation of successful guesses above the mean expectation. If all the trials are pooled, the calculated probability of obtaining so large a deviation in either direction by chance alone is less than 0·005, which by convention is quite significant. The experimental result has been therefore reinterpreted in terms of a new phenomenon, clairvoyance, which the experiment was not designed to show.

In later experiments, more unexpected 'significant' deviations appeared in what should have been chance results, and new labels were used for explaining them. For example, correspondences between lists of guesses and packs of cards shuffled and scored after the guesses had been made were referred to as 'precognition'. (This expression was also used, with less justification, for describing a simple displacement of hits.) Later still, correspondences between the faces falling uppermost on a die and certain arbitrarily (or randomly) chosen 'target faces' were taken as evidence that an experimenter could influence the fall of the die merely by thinking about it; this was called 'psychokinesis'.

For reasons I shall make clear below, the claim to have demonstrated psychokinesis is theoretically of more interest than the claims to have demonstrated telepathy and the other phenomena. However, it should be pointed out that the results of the 'psychokinesis' experiments are generally indistinguishable from those of experiments in telepathy, etc. The decline in scoring within the temporal unit[3] ('beginners' luck' curve) is equally prominent; the findings, however 'significant', are not susceptible to demonstrable repetition[4]; and control series tend to be as curious as the main series[5]. But here, unlike the case of Coover's experiment, experimenters have not been able to explain the curious results of their 'psychokinesis' controls in terms of any new phenomenon, and have had to fall back upon explanations in terms of more psychokinesis: such 'explanations' therefore beg the question at issue.

A test of statistical significance depends upon the randomization of the set of observations. As Fisher[6] points out, this is "the physical basis of the validity of the test". It must therefore be assumed for experimental purposes that the means of randomizing, such as shuffling cards, throwing dice or refinements of these methods, will not appear to be influenced at all by what the experimenter is thinking about. If we may not assume this, then we have no empirical reason for considering the test to be valid. But psychical research workers now claim to show that in many cases the experimenter does appear to influence the means of randomizing merely by thinking about them: yet in appraising their results these workers depend solely on a test of significance which is valid only if the results they claim do not in fact occur.

This is a curious state of affairs. It is clear that, by the very logic of the situation, no mere statistical test of significance can suffice to demonstrate the existence of a causal relationship between the falls of dice and the thoughts of their observers, simply because to apply the test in such a case is to assume a contradiction. Equally, if 'significant' results are obtained in a well-designed and properly observed 'psychokinesis' experiment, then all the statistical 'demonstrations' of telepathy, etc., must now be called into question, since they, like the dice experiments, rely on statistical significance only, and not upon demonstrable repetition or comparison with controls. The claim for psychokinesis has thus made nonsense of these claims for telepathy, etc., besides being itself, on the evidence, a nonsensical claim.

Since it is clearly meaningless to speak of 'influencing' random-producing agents on evidence which is nothing more than statistically significant, and since there nevertheless exist a number of highly 'significant' results in the best designed and most rigorously observed experiments, the simplest explanation left open to us is that the calculus which leads us to interpret these results as significant is itself misleading. The only purpose of devising criteria of statistical significance is to provide a guide to indicate what observations we make will be repeatable; that is, the concept of *statistical* significance is useful only as a guide to *inductive* significance. But statistical significance in psychical research is clearly not a guide to inductive significance; it is therefore incumbent upon us to try the hypothesis that the results of the best-designed and most rigorously observed experiments in psychical research are chance results after all, and that the concept of chance can cover a wider natural field than we previously suspected.

This hypothesis is equivalent to the assumption that random series do not in fact 'behave' quite as we have hitherto assumed they do. If this is true, then it should be noticeable in fields where randomizing processes have been used for other purposes than psychical research. In later papers I hope to show that the present criterion of statistical significance appears to have been systematically misleading in certain zoological experiments in much the same way as it appears to have been in psychical research. In addition I have evidence, also to be published shortly, that statistically significant results similar to those of psychical research are obtainable simply by making selections in published tables of random numbers as if the tables were themselves the data of a psychical research experiment. This procedure, which consists in matching randomly selected columns of random digits and scoring successes as they are scored in columns of recorded cards and guesses, produced, in the first experiment, results which differed from the mean expectation by more than three standard deviations; and these results, together with later ones, are indistinguishable from those produced by orthodox psychical research. The deviations are not as large as have been found in some experiments in telepathy, etc.; but what is chiefly interesting is that such results should be 'significant' at all, and that the degree of 'significance' should in fact be as high as it is.

There are some who might suggest, following Keynes[7], that all these results cannot show anything other than that the randomizing processes used were not of the best quality, thereby implying that if we had used better randomizing agents, results of this kind would not appear. However, by now such a wide variety of randomizing processes have been claimed as objects of successful 'psychokinesis' experiments, all giving results of a characteristic form, that it would be surprising suddenly to find one which was in this respect different from all the others; and if we are finally reduced to saying that all the random series we can produce are imperfect in this way, it is equivalent to saying that there is something wrong with our concept of randomness as a model for describing what we actually observe. This possibility, which Keynes ignored (though Venn[8], writing much earlier, did not), is one which accumulated evidence is now forcing us to consider. There is, however, another reason why this possibility is worthy of consideration.

The concept of physical randomness upon which applied probability theory depends is necessarily vague in much the same way as the concept of physical simultaneity is vague. Attempts to remove the vagueness in the case of the randomness concept by using it only for series of infinite length do not touch the empirical problem since they leave us with no practical means of ever completing a test for randomness. As a result, the criterion for a random series is extremely arbitrary, being merely that there is no *obvious* formula for its construction; and what is obvious, of course, varies between observers. Perhaps it should therefore be a matter of some surprise that present probability theory applied to science in fact works as well as it does; and if we could discover how it is that it does work so well, we might be able to see how it is that it does not appear to work quite well enough.

I wish to express my gratitude to the Perrott Electors of Trinity College, Cambridge, under whom the new description of this psychical research problem was originally made, and to Prof. A. C. Hardy, of Oxford, who generously provided a grant for the research to continue in his Department. I should also like to thank Sir Ronald Fisher, by whose writings and conversation I have been greatly helped.

EVIDENCE FOR 2-CHAIN HELIX IN CRYSTALLINE STRUCTURE OF SODIUM DEOXYRIBONUCLEATE

By ROSALIND E. FRANKLIN* and R. G. GOSLING

Wheatstone Physics Laboratory, King's College, London, W.C.2

WATSON AND CRICK[1] have proposed a structure for sodium deoxyribonucleate consisting of two co-axial helical chains related by a diad axis. We have shown[2] that the main features of their structure are consistent with certain important features of our X-ray diagrams of structure *B* (the high-humidity less-ordered form of the salt). A subsequent closer investigation of density and water content in relation to the prominent equatorial spacing, and also of equatorial intensities calculated from a projection of the proposed structure (kindly provided by Watson and Crick), makes it clear that in detail the structure is not consistent with the observed equatorial reflexions. Both density and intensity considerations lead us to favour a more compact helical structure in which the phosphorus atoms lie on a helix of radius about 8·5 A. rather than 10 A. This value also lies within the range of spread of the more diffuse layer-line peaks.

We are more concerned here, however, with evidence which confirms in principle the type of structure suggested by Watson and Crick, than with criticism on points of detail.

If a 2-chain helical molecule exists in structure *B*, then such a molecule, in modified form, must also exist in structure *A* (the crystalline form obtained at 75 per cent relative humidity), since the change $A \rightleftarrows B$ is readily reversible. The purpose of this communication is to point to evidence for a 2-chain helical molecule in structure *A*.

For structure *A* we have measured the positions and intensities of reflexions and have calculated the cylindrically averaged Patterson function[3]. The work is described in detail elsewhere[4]. The Patterson function is reproduced in Fig. 1. The theoretical curve for the Patterson function of a smooth helix of radius 9·0 A. is also shown (curve (i)). The very strong peak at height $c = \frac{1}{2}$ on the fibre axis suggests that the phosphate groups of the two chains are separated by approximately $\frac{1}{2}c$. We therefore added to Fig. 1 curve (ii), which completes the theoretical Patterson function for two smooth co-axial helices separated by $\frac{1}{2}c$ (c is the pitch of the helix). Curves (i) and (ii) together clearly pass through a large proportion of the important Patterson peaks. Moreover, if we take into account the fact that the real structure contains, not smooth helices, but phosphate groups equally spaced along such helices, the agreement is even better.

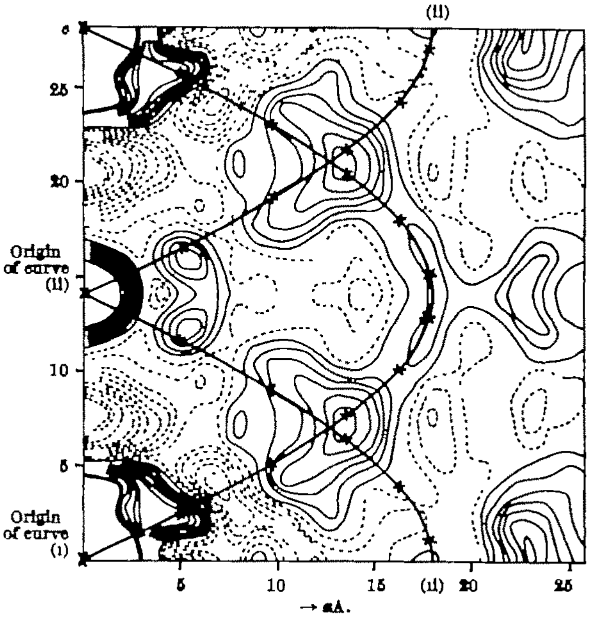

Fig. 1. Cylindrical Patterson function of crystalline sodium deoxyribonucleate. ×, theoretical peak for *intra*-helical P – P vector

The only near-meridional reflexion in the X-ray diagram of structure *A* is a rather weak one on the eleventh layer-line. This suggests that there are eleven nucleotides per turn of the helix. (This is sufficiently near to the number ten, found for structure B[1,3,4], for the reversible transformation $A \rightleftarrows B$ to be plausible.) Further, we may suppose that the well-resolved peak at 5·7 A. from the pseudo-origin peak at $c = \frac{1}{2}$ represents a P – P vector, and this distance is exactly that between neighbouring phosphorus atoms if eleven are equally spaced along one turn of a helix of radius 9 A. In Fig. 1 we have marked with a cross the theoretical positions of intra-molecular Patterson peaks to be expected for this arrangement, assuming that the phosphorus atoms on one helix lie vertically above those on the other. The agreement with the observed Patterson peaks is seen to be remarkably good.

In Fig. 2 we have marked on the Patterson function the positions of all inter-molecular P – P vectors obtained when, in the unit cell described below, there is one molecule (that is, two chains) associated with each lattice point. The circles in Fig. 2 have each only 1/11 of the weight of the crosses in Fig. 1, and 1/22 and 1/44 of the weight of the pseudo-lattice points (relating phosphate residues only) shown by crosses near the half-cell height in Fig. 2. The lattice points relating the whole structure are denoted by larger crosses near to the origin level in c. In addition to this weighting, for correlation with the cylindrically averaged Patterson function, the weight of each calculated peak should be considered as inversely proportional to x, since in averaging it must be spread over a circle of radius x. When these factors are taken into account, it will be seen that agreement between calculated and observed Patterson peaks is still good.

---

* Now at Birkbeck College Crystallographic Laboratory, 21 Torrington Square, London, W.C.1.

Space group, density and the unit cell. Using the cylindrical Patterson function, we have been able to identify the lattice vectors (indicated in Fig. 2) and hence to index all 66 observed reflexions. The unit cell is face-centred monoclinic having $a = 22 \cdot 0$ A.; $b = 39 \cdot 8$ A.; $c = 28 \cdot 1$ A.; $\beta = 96\frac{1}{2}°$. If the unit cell is truly monoclinic, the space-group can only be $C2$, since the molecule contains asymmetric carbon atoms. Again, since the structure of the phosphate sugar backbone chain is non-centric, the symmetry axis cannot pass through such a chain, but must relate the chains one to another in pairs. There must, therefore, be an even number of chains associated with each lattice point.

In order to calculate the number of nucleotides in the unit cell, it is necessary to know both the density and the water content. Unfortunately, these quantities can only be measured on a polycrystalline mass, and there must remain some uncertainty as to the true density and water content of the crystallites. Our measurements[5] gave a density of 1·47 gm./c.c. at 75 per cent relative humidity and a water content of about 40 per cent of the dry weight (or about $8H_2O$ per nucleotide). We have confirmed that the specimens used for these measurements were in the form of structure *A* and not structure *B*. These results correspond to twenty-three nucleotides per lattice point, which is in reasonable agreement with the suggestion that the primitive unit cell contains eleven nucleotides on each of two chains.

The three-dimensional Patterson function. After establishing the unit cell and indexing the reflexions, the complete three-dimensional Patterson function was calculated. This will be published and discussed in detail elsewhere. The $a-b$ sections at heights $c = 0$ and $c = \frac{1}{2}$ are shown in Fig. 3. The very strong peak at $a = b = 0$, $c = \frac{1}{2}$ suggests a pseudo-halving of the unit cell. On the other hand, all features of the zero section other than the origin peak are almost entirely reversed in the section $c = \frac{1}{2}$. This at once suggests that only a part of the structure repeats at $c = \frac{1}{2}$. This is exactly what would occur for two co-axial chains related by a diad axis, as suggested by Watson and Crick. The phosphate groups repeat at $c = \frac{1}{2}$, as indicated in Fig. 1; but, since the two chains run in opposite directions, this will not be true of the rest of the molecule.

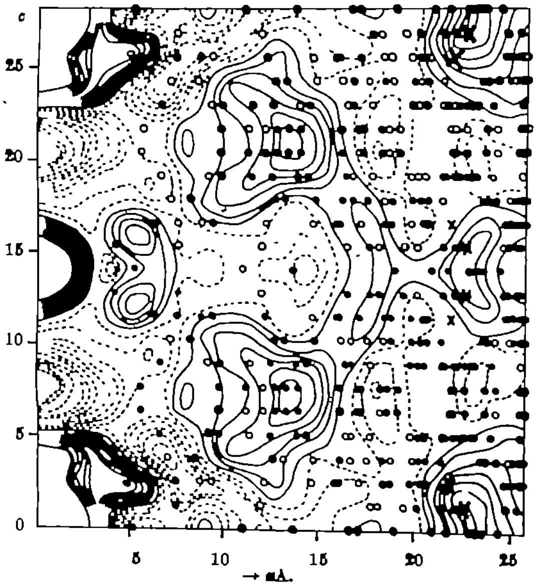

Fig. 2. Cylindrical Patterson function of crystalline sodium deoxyribonucleate. O, theoretical peak for inter-helical P – P vector

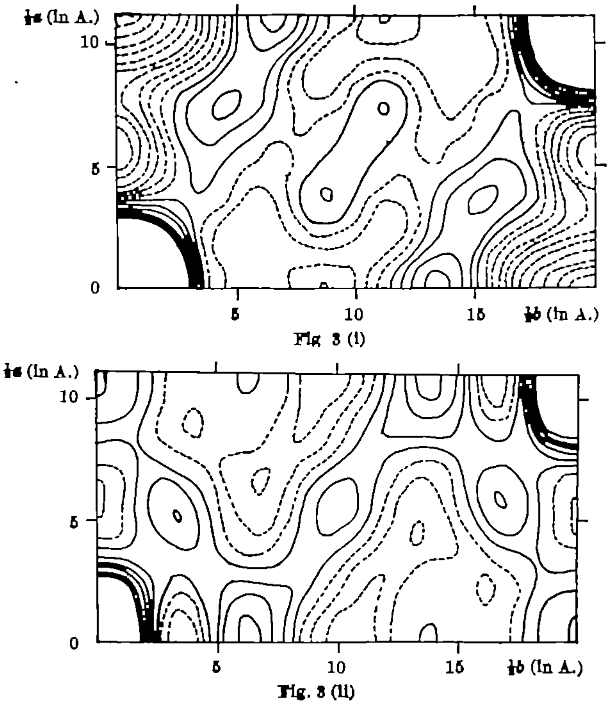

Fig. 3 (i)

Fig. 3 (ii)

Three-dimensional Patterson function of crystalline sodium deoxyribonucleate. Sections in $a-b$ plane at (i) $c = 0$, (ii) $c = \frac{1}{2}$

Relationship between structure A and structure B. In conclusion, we suggest that the unit in structure *A* is, as in structure *B*, two co-axial helical chains running in opposite directions. In the change from *B* to *A* the number of residues per turn increases from ten to eleven and the pitch of the helix decreases from 34 A. to 28 A. In structure *A* the phosphate groups lie on a helix of radius 9 A., with a separation of approximately $\frac{1}{6}c$ between the phosphate groups of the two co-axial chains.

The vertical component of the inter-base distance is thus decreased from 3·4 A. in structure *B* to 2·55 A. in structure *A*. This indicates that in structure *A* the planes of the bases cannot be perpendicular to the fibre axis. The positions of the strong reflexions on the sixth, seventh and eighth layer-lines suggest that the angle of tilt is about 25°.

We are grateful to Prof. J. T. Randall for his interest and encouragement. One of us (R. E. F.) acknowledges the award of a Turner and Newall Fellowship.

D-Enzyme: a Disproportionating Enzyme in Potato Juice

THE synthesis of amylose is catalysed by the enzyme phosphorylase, which effects a reversible transglucosylation reaction between glucose-1-phosphate and chains of α-1 : 4-linked glucose units. Hitherto this has been the only known plant enzyme capable of effecting the synthesis of α-1 : 4-glucosidic linkages. We now have to report the discovery of an enzyme in the potato which can effect the synthesis and degradation of (short) amylose-type chains by transglucosylic action. The enzyme was detected in greatest amount in the alcohol-precipitated fraction of potato juice which also contains the greatest amounts of *Q*-enzyme. The latter enzyme catalyses the conversion of amylose into amylopectin, which involves the simultaneous splitting of α-1 : 4-links and synthesis of α-1 : 6-links (an irreversible transglycosylation)[1]. The new enzyme manifested itself when a *Q*-enzyme preparation was allowed to act on the linear maltosaccharides produced by the partial acid hydrolysis of amylose[2]. Two effects were noticed. First, iodine-staining material was synthesized from the achroic saccharides and, secondly, paper chromatograms of the digests revealed that the substrates had been disproportionated into products of higher and lower molecular weight, the latter including glucose. For this reason, we have provisionally named the new factor *D*-enzyme.

D-enzyme brings about rapid disproportionation of malto-triose, -tetraose, -pentaose, -hexaose and -heptaose ; but action in the case of maltose is doubtful. Glucose itself is not a substrate. The greater the molecular weight of the maltosaccharide substrate, the greater is the final intensity of iodine stain. With maltohexaose the iodine colour changes through brown and red to purple-red, the intensity then remaining very nearly constant for prolonged periods of digestion. On addition of glucose to such a digest, however, the iodine-staining power disappears rapidly. The simplest explanation of these results would be that the action of *D*-enzyme is to effect the transfer of glucose units, either singly or severally, from one molecule of substrate (donor) to an acceptor molecule, which may be either a maltosaccharide or glucose. Furthermore, in view of the fact that the products stain with iodine, it would seem probable that the linkage synthesized is of the α-1 : 4-chain-forming type.

Proof of the unbranched character of the products was obtained by treatment of maltotetraose with *D*-enzyme and afterwards with salivary α-amylase. Charcoal fractionation of the hydrolysate yielded only glucose, maltose and maltotriose, and in amounts corresponding to 97 per cent of the maltotetraose taken. This result demonstrates that *D*-treated maltotetraose does not contain any substantial proportion of branched structures. Thus waxy maize starch, in which α-1 : 6- and α-1 : 4-links are present in a ratio of 1 : 23, is hydrolysed by α-amylase to yield maltose (41·8 per cent), maltotriose (28·4 per cent) and 29·8 per cent of limit dextrins containing both types of linkage[3].

While it is clear that *D*-enzyme catalyses redistribution reactions among linear maltosaccharides, the pattern of its action is still obscure. The most significant observation concerns the place of maltose in this scheme. As already mentioned, *D*-enzyme appears not to utilize maltose as a substrate and, moreover, maltose is not formed (except in traces and only after prolonged action) when *D*-enzyme acts on other maltosaccharides. Thus the lower molecular weight products from each maltosaccharide always contain in addition to glucose every lower linear maltosaccharide except maltose. Possible explanations of these effects are being considered, but further work is obviously necessary and is proceeding.

It seems evident that the role of glucose in causing removal of iodine-staining material (see above) is due to its functioning as an acceptor for the transferring action ; it cannot act as a donor. In a parallel experiment, *D*-enzyme was allowed to act on maltohexaose, and glucose labelled with carbon-14 was then added. When the digest became achroic the products were fractionated on paper. Radioactivity was found to be distributed throughout the zones corresponding to the maltosaccharides.

Two bacterial enzymes are known which catalyse somewhat similar reactions. Amylomaltase from *E. coli*, which synthesizes amylose-like molecules from maltose[4], is clearly different from *D*-enzyme. The Schardinger dextrinase action reported by Norberg and French[5] does, however, bear a certain resemblance to that of *D*-enzyme. The *in vivo* function of *D*-enzyme can, at the moment, be a matter for conjecture only ; but it may either provide 'primers' for phosphorylase synthetic action, or itself catalyse the synthesis of amylose. The latter possibility carries with it the implication that phosphorylase function may be confined to the degradation of starch.

We are grateful to the Agricultural Research Council for financial assistance, and wish also to thank Dr. Helen Porter for the gift of carbon-14 starch and Dr. L. H. May for measurement of the radioactivity.

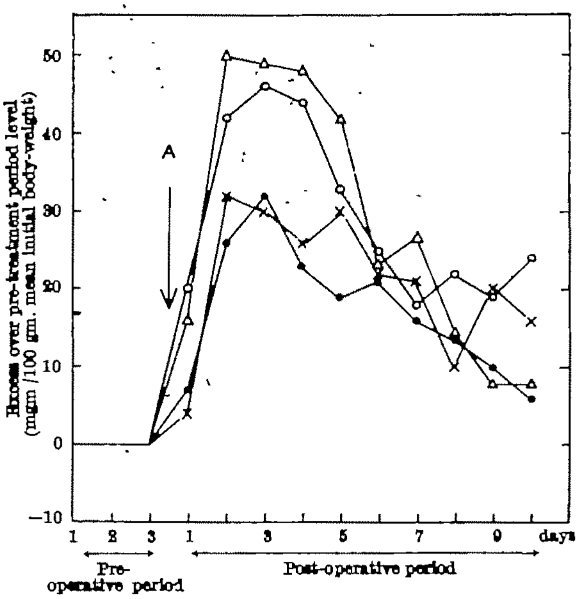
Cortisone and the Metabolic Response to Injury

THE pattern of the metabolic response of man to injury (for example, fracture of a long bone), in particular its effect on protein catabolism, has been under investigation for some time by one of us[1] as this phenomenon is of basic importance to our understanding of protein metabolism in general. The reaction is characterized in man by a marked increase in the urinary excretion of nitrogen and sulphur, which reaches a peak from the fourth to the eighth day after the injury and then slowly declines. There is also a loss of phosphorus and potassium. This phenomenon has been confirmed by many workers and in other forms of injury[2]. Cuthbertson, McGirr and Robertson[3] have also found the same thing to occur in the rat, though rather earlier. The losses appear to be more general than local in origin.

In 1942, Albright[4] first suggested the view that the catabolic impulse of the alarm reaction of Selye may be due to an excessive production by the adrenal cortex of '*S*-hormone' (now identified as the gluco-corticoids), simultaneously with a decreased production of '*N*-hormone' (now identified as adrenal testoids). In 1947, Ingle, Ward and Kuizenga[5] found that the negative nitrogen balance, which characteristically develops following fractures, seems to require the presence of adrenal cortical hormones, but is not caused specifically by an increase in the secretion of the cortical hormones during stress. Selye[6] has suggested that here we are dealing with a peripheral synergism between the corticoids and other factors produced by stress. Kochakian and Robertson[7] have shown that in the mouse this metabolic effect of cortisone can be divided into at least two sharply defined phases: a rapid mobilization of readily available protein stores, followed by a period of metabolic readjustment or adaptation, the striking feature of the first phase being the rapid decrease in body-weight and extra nitrogen excretion, and this seems to be concomitant with a maximum involution of the lymphatic tissues. While the mobilization of protein from lymphoid tissue is considered by these authors to be a specific property of the gluco-corticoids, it seems doubtful if the lymphatic tissue is adequate unless it is larger than we surmise. Ingle[8] has also reported a protein catabolic phase in rats receiving cortisone which disappeared after about ten days. Eliel *et al.*[9] have pointed out that patients in whom hyperadrenocorticism occurred spontaneously or was induced by administration of adrenocorticotrophic hormone or cortisone exhibited losses of nitrogen, potassium and phosphorus strikingly resembling those of operative trauma, a similarity already pointed out by one of us.

As the period of increased protein catabolism which follows an injury such as a fracture in the rat[8] seems to have much in common with the results of implanting cortisone, it seemed appropriate to determine if the protein catabolic effects of injury and cortisone administration in the rat were similar in their general character and what would happen if they were superimposed. For this purpose the males of several litters of Rowett Institute stock rats at approximately three months old and around 300 gm. body-weight were divided into four treatment groups, a decision based on earlier trials. These groups were: (1) subcutaneous implantation of 25 mgm. cortisone acetate; (2) fracture of femur by open operation through incision comparable to that required for fracture; (3) subcutaneous implantation of 50 mgm. cortisone acetate; (4) fracture + implantation of 25 mgm. cortisone acetate subcutaneously. The implantations and fracture were all done under ether anaesthesia. Sham-operated controls showed little disturbance of nitrogen metabolism, a finding in keeping with earlier observations.

The animals were maintained for some time before treatment and continuously thereafter on a constant stock food intake.



×—×—, Cortisone, 25 mgm. (6 rats); ●—●—, fracture (6 rats); O—O—, cortisone, 50 gm. (6 rats); △—△—, fracture + cortisone, 25 mgm (5 rats). *A*, arrow indicates cortisone (25 or 50 mgm.), fracture, or fracture + cortisone (25 mgm.)

It will be seen from the graph and the table that in the rat the effects of implanting subcutaneously one 25-mgm. tablet of cortisone acetate and of fracture of a femur are similar in character and magnitude as measured by change in urinary nitrogen. On superimposing upon the implantation of one 25-mgm. pellet either a simultaneous fracture or a second 25-mgm. pellet through the same incision, the net effects are again very similar, and greater than that of fracture or of one pellet separately, although not so great as if they were additive. S.E. of difference between the mean of the first two treatments on one hand and that of the other two is ± 30 (13 d.f.).

The evidence thus suggests strongly that the effect of fracture of a femur in the rat is roughly equivalent to the effect of slowly liberating 25 mgm. of cortisone (calculated as acetate) from the adrenal cortex, and that increasing the stimulus (as measured by cortisone) increases the response, possibly on a progressively reducing scale. Whether we can go further and say that the effect of such an injury is to cause the liberation of such a quantity of gluco-corticoid from the adrenal cortex is not so certain.

The magnitude of these responses is apparently conditioned by the amount of hormone implanted and by the presence or absence of injury. It seems unlikely that the results with cortisone are exaggerated responses to the injury caused by a plethora of hormone at the act of implantation, as might possibly be deduced from the observations of Engel[10]. The similarity in response of two pellets of cortisone to one pellet plus fracture and the almost identical separate effects of one pellet and fracture render this very doubtful.

It is difficult to account for these findings in the light of the observations of Ingle *et al.*[5] to which reference has already been made, unless it is presumed that the effect of injury is not to evoke a liberation of hormone from the adrenal cortex but to cause

INCREASE OF URINARY NITROGEN VALUE OVER BASAL FOR 10 DAYS FOLLOWING TREATMENT

	Cortisone acetate (25 mgm.)	Fracture	Cortisone acetate (50 mgm.)	Cortisone + fracture acetate (25 mgm.)
Increase in mgm. nitrogen per 100 gm. body-weight	196	202	297	269

some change in the circulating hormone which then induces the catabolic phenomenon, and that this effect can be replicated by the changes induced by the implantation of 25 mgm. of cortisone acetate.

We are indebted to the Medical Research Council for a supply of 'Cortone' (Merck).

Reversal of the Antibacterial Activity of Polymyxin by Divalent Cations

THE antibiotic polymyxin has been used with some success in the treatment of *Pseudomonas aeruginosa* infections of burns[1]. Previous studies have shown that the addition of polymyxin to washed suspensions of this organism caused a release of pentose, phosphate and materials which had an absorption maxima at 260 mμ[2,3]. The leakage was a maximum in the presence of concentrations of polymyxin which killed 99 per cent of the cells, higher concentrations inhibiting the leakage.

When washed cells were treated with polymyxin in the presence of magnesium, it was found that the leakage of soluble constituents from the cells did not occur (see graph). This 'protective' action of magnesium could be reversed by the addition of 2 molecules of citrate per atom of magnesium present.

Growth experiments using a complete growth medium (tryptic digest of casein which contained the equivalent of 3 per cent (w/v) casein) showed that the limiting inhibitory concentration of polymyxin could be increased by as much as thirty times by the addition of magnesium (Table 1). However, in these experiments the effective concentration of magnesium could not easily be determined, as there was some precipitation with the constituents of the medium.

Table 1. INCREASE IN THE LIMITING INHIBITORY CONCENTRATION OF POLYMYXIN IN THE PRESENCE OF MAGNESIUM

An inoculum of c. 10^6 cells/10 ml. was used. + indicates visible growth after incubation for 24 hr. at 30°

	Concentration of polymyxin (μgm./ml.)

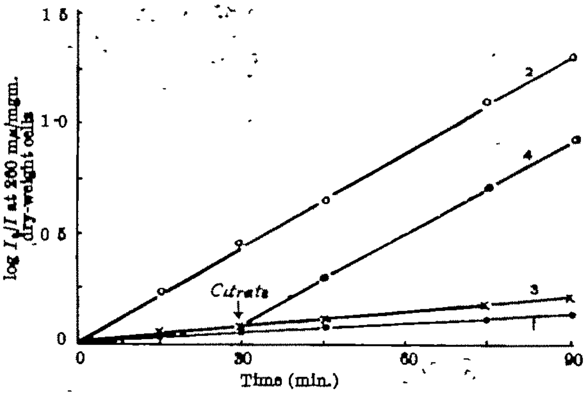
0·0125 *M*	+	+	+	+	+					
0·025 *M*	+	+	+	+	+	+	+			
0·05 *M*	+	+	+	+	+	+	+	+	+	



Curve 1, leakage of materials with an absorption maximum at 260 mμ from washed cells of *Ps. aeruginosa* suspended in 1 per cent (w/v) sodium chloride solution. Cell density 1 mgm. dry weight of cells per ml. Temperature 30°.

Curve 2, same as (1) + 25 μgm. polymyxin/ml.

Curve 3, same as (2) + magnesium sulphate to give a final concentration of 0·0025 *M*.

Curve 4, same as (3) + sodium citrate (final concentration 0·005 *M*) after 30 min.

When suspensions of washed cells (containing about 2 × 10^9 viable cells/ml.) were treated with 15 μgm. polymyxin/ml. for 5 min. at 30°, less than 10 per cent of the cells remained viable. In the presence of *M*/400 magnesium, 70–90 per cent of the cells were viable. Similar results have been obtained with other non-toxic divalent cations; for example, calcium, manganese and ferrous iron (Table 2). The results of preliminary experiments have indicated that the presence of such cations prevents the absorption of polymyxin by the cells.

Table 2. REVERSAL OF THE ANTIBACTERIAL ACTIVITY OF POLYMYXIN BY DIVALENT CATIONS

Washed cell suspensions (c. 2 × 10^9 viable cells/ml.) treated with polymyxin (15 μgm./ml.) at 30° in the presence or absence of the cations shown below. After 5 min., 1 ml. samples were withdrawn and transferred to 99 ml. sterile saline. Suitable dilutions were plated out in growth-medium containing 2 per cent agar, and the colonies counted after incubation for 48 hr. at 30°. All figures are the mean of four experiments

Treatment of cell suspensions	Plate count	Dilution factor	Survivors (per cent)
Untreated	262	10^7	—
+ 15 μgm. polymyxin/ml.	166	10^6	6
+ 15 μgm. polymyxin/ml. + 0·0025 *M* Mg^{++}	216	10^7	83
+ 15 μgm. polymyxin/ml. + 0·0025 *M* Mn^{++}	184	10^7	71
+ 15 μgm. polymyxin/ml. + 0·0025 *M* Ca^{++}	236	10^7	90
+ 15 μgm. polymyxin/ml. + 0·0025 *M* Mg^{++} + 0·005 *M* citrate	188	10^6	7

There seem to be two possible explanations of the above results: (1) competitive absorption between polymyxin and the non-toxic cations for sites on or in the cells; (2) formation of a polymyxin – metal ion complex with the resultant inactivation of the antibiotic. In view of the high magnesium/polymyxin ratio (c. 400 atoms magnesium per molecule of polymyxin) required to reverse the antibacterial activity, the former hypothesis would seem to be more reasonable.

Valko and DuBois[4] reported the protective action of relatively harmless cations against the action of toxic, surface-active cations, and suggested that the basis for the antibacterial action of such cations could be satisfactorily described in terms of cationic exchange.

Bliss, Chandler and Schoenbach[5] found that polymyxin was inactivated by soap, lipositol and other substances known to antagonize cationic detergents. The results reported above, together with those of Newton[2,3] and Few and Schulman[6], further support the resemblance between cationic detergents and polymyxin, although cationic detergents are generally far more effective against Gram-positive than Gram-negative organisms, whereas polymyxin is more active against the latter.

A Colorimetric Estimation of Sugars using Benzidine

A SOLUTION of benzidine in acetic acid has been used by Horrocks and Manning[1] as a chromatographic spray reagent for the detection of sugars. A quantitative technique, using this reagent, has been perfected and found to be satisfactory for the majority of common sugars (cf. McCance[2]) and their methylated derivatives with the exception of ketoses. Concentrations as low as 0·1 mgm./ml. were estimated, with errors of less than 3 per cent.

The procedure for estimation was as follows. 1 ml. of sugar solution and 5 ml. of 0·2 per cent (w/v) benzidine in glacial acetic acid were placed in a boiling-tube and heated in a vigorously boiling water-bath. The heating time necessary for maximum colour production varied with the nature of sugar being estimated (see table). After cooling to room temperature in running water, the orange-yellow coloration was measured with a Hilger Spekker (Ilford No. 601 filter). The relationship between concentration and absorption was linear for the following sugars:

Sugar	Heating time (min.)
Glucose	30
Mannose	,,
Galactose	,,
Glucuronic acid	,,
Galacturonic acid	,,
Rhamnose	,,
Arabinose	15
Ribose	,,
Xylose	,,
2 : 3 : 4-Trimethyl xylose	60
2 : 3 : 6-Trimethyl glucose	,,
2 : 4 : 6-Trimethyl glucose	,,
2 : 3 : 4 : 6-Tetramethyl glucose	,,
Sucrose	,,
Maltose	,,
Raffinose	,,

Polysaccharides have been analysed by the new method, quantitative separation of the monosaccharide components being effected by paper partition chromatography. Sugars were extracted from the paper with hot 90 per cent methyl alcohol, and the methanolic sugar solution evaporated down to a syrup *in vacuo*. The required volume of distilled water was then added, and a 1-ml. aliquot of the solution taken for analysis. Standard sugar mixtures separated by the above procedure were estimated with errors of 3–5 per cent.

The mechanism of the reaction has been examined and it appears that molecular equivalents of benzidine and sugar (having a free or easily accessible aldehyde group) combine to give a coloured compound.

The mild nature of the reagents used, and the wide range of sugars which can be estimated, are the two main advantages of the new method.

A detailed report of experimental method, results, and applications will be published elsewhere.

Isolation and Biochemical Function of the Golgi Substance

RECENT studies have demonstrated the positive image of the Golgi substance in epithelial cells of the mouse epididymis with the phase-contrast microscope[1]. *In situ*, the Golgi substance was found to possess characteristic optical properties with phase-contrast and dark-field illumination, and to be completely refractory to staining with methylene blue and neutral red. Examination of cells of the head of the epididymis of the rat and the mouse immediately after or during crushing clearly indicated that the Golgi substance retained its general form and its specific optical properties upon release from its intracellular environment. Experiments to determine the most suitable medium for the maintenance of the Golgi substance extracellularly indicated that the presence of 0·34 *M* sodium chloride was essential and that the addition of sucrose in concentrations ranging from 0·25 to 1·25 *M* to the saline medium had no appreciable effect on the morphology, optical properties or stability of the Golgi substance.

The isolation of the Golgi substance was accomplished by a modification of the method of Brakke[2], which we have used with some success in the fractionation of isolated liver mitochondria[3]. A 20 per cent homogenate of rat epididymis in 0·25 *M* sucrose was prepared[4], layered over a sucrose density-gradient consisting of 1·0-ml. layers of 0·335, 0·636, 0·957 and 1·11 *M* sucrose, each containing 0·34 *M* sodium chloride, and centrifuged for 60 min. at 35,600 r.p.m. (108,000 *g* average) in the *SW* 39 horizontal rotor of a Spinco Model *E* ultracentrifuge. The Golgi substance was found to sediment in a sharp yellowish band 2–3 mm. wide at the bottom of the 0·636 *M* sucrose layer (Fig. 1); and since clear layers at least 5 mm. wide were present on either side of the Golgi band, it was found possible to separate this band by cutting the centrifuge tube at appropriate points. Microscopic examination of the separated Golgi layer showed that it contained large clumps of bodies with the optical properties under phase- and dark-ground illumination (Fig. 2) characteristic of the Golgi substance as it is seen in the intact cell and extracellularly

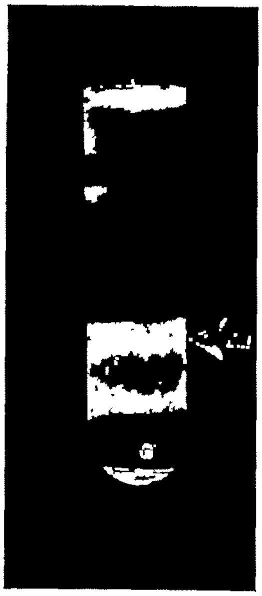

Fig. 1. Photograph of tube after centrifuging epididymis homogenate layered over sucrose density-gradient. Note bands of particulate material at regular intervals above sediment. The first band above the sediment consisted of submicroscopic particles, and the second (arrow) contained the Golgi substance. Fat was found at the very top of the tube surmounting a layer of the soluble proteins of the homogenate

in crushed preparations. In addition, some submicroscopic material was also observed in this layer; but the main mass of the submicroscopic particles of the epididymis homogenate sedimented as a sharp band at the bottom of the 0·957 *M* sucrose layer. It is noteworthy that no material resembling free lipid could be identified in the band containing the Golgi substance, nor could any material stainable with neutral red or methylene blue be observed in this layer. Furthermore, Golgi material was not observed in any other parts of the centrifuge tube. Thus it is believed that a relatively complete separation of a sedimentable component or components of the Golgi substance of the rat epididymis has been achieved.

The histochemical observations[5], which indicated a high concentration of alkaline phosphatase in the region of the Golgi substance of the epithelial cells of the intestine, prompted us to study the distribution of this enzymatic activity in the separated epididymal fractions. The results are given in the accompanying table, and show that alkaline phosphatase activity was greatly concentrated in the layer containing the isolated Golgi material, thus apparently confirming the histochemical results.

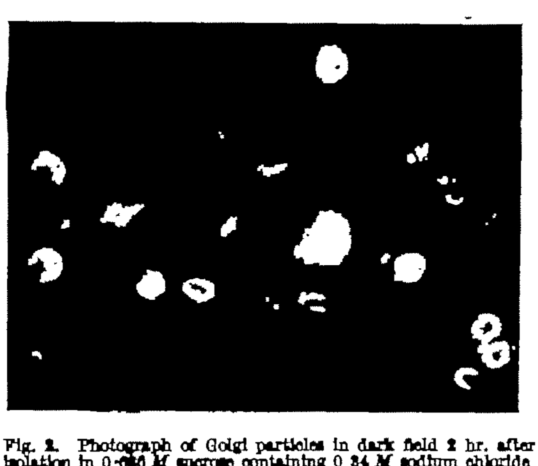

Fig. 2. Photograph of Golgi particles in dark field 2 hr. after isolation in 0·880 *M* sucrose containing 0·34 *M* sodium chloride. The majority of the particles have a refractile, crescent-shaped or horseshoe-shaped periphery with a less refractile centre. × 3,000

INTRACELLULAR DISTRIBUTION OF ALKALINE PHOSPHATASE ACTIVITY AND TOTAL NITROGEN IN RAT EPIDIDYMIS

The results are presented in terms of 100 mgm. of fresh tissue or its equivalent

Fraction	Composition of fraction	Position in centrifuge tube	Total nitrogen	Alkaline phosphatase activity*	
				Total	Per mgm. nitrogen
Whole homogenate			1·68	101·5	60
1	Fat-soluble material	Upper	0·916	69·5	76
2	Golgi bodies, some submicroscopic particles	Middle	0·091	43	473
3	Submicroscopic particle layer mitochondria nuclei, sperm	Lower	0·796	37	46·5

* Expressed as micrograms phosphorus released in 15 min. at 37° C. from sodium glycerophosphate at pH 9·4.

Further studies on the chemical composition and enzymatic constitution of the Golgi substance are in progress and will be reported in detail elsewhere.

Occurrence of Cholinesterase in *Tenebrio* and *Tribolium*

Lord and Potter have reported[1] that they could not obtain preparations of *Tenebrio molitor* larvæ or *Tribolium castaneum* adults which could hydrolyse acetylcholine. This failure is surprising in view of the supposed ubiquity of cholinesterase "in conductive tissue throughout the whole animal kingdom"[2], and is of importance because of its bearing on the question of the mode of action of organophosphorus insecticides. Since both insects are killed by low concentrations of tetraethyl pyrophosphate (TEPP), Lord and Potter's observations would indicate that the significance of its anti-cholinesterase effect is not as great as had been thought[3]. Although the authors stated that "no persistent attempt was made to prepare an extract hydrolysing ACh", their work has been taken to show[4] the absence of cholinesterase in these insects. In their principal preparation, the supernatant from their homogenates was treated with half its volume of ethyl alcohol. The inability of the resultant solution to hydrolyse acetylcholine is not surprising in view of the anti-cholinesterase activity of ethyl alcohol[5]. Furthermore, the brei was centrifuged at two stages, and the centrifugates rejected; Babers and Pratt[6] have shown that, in the honey-bee, five-sixths of the cholinesterase is in the centrifugate of whole brei.

Experiments are here reported using less drastic treatment. The insects were homogenized in distilled water in a Potter–Elvehjem homogenizer (ice-cooled), and 2·5 ml. (usually) of whole brei were used. The standard Warburg technique was employed, using 1 ml. of buffer (0·31 *M* sodium chloride, 0·67 *M* sodium bicarbonate, 0·0024 *M* potassium chloride, 0·0012 *M* calcium chloride), and tipping in 0·2 ml. acetylcholine bromide (0·022 *M*). An atmosphere of 5 per cent carbon dioxide in nitrogen was used at a temperature of 25° C. The ensuing procedure and analysis of results were as described by Aldridge *et al.*[7]. Determinations in triplicate were made for each brei.

For *Tenebrio*, the b_{30} per larva was 11·1 µl. ± 0·4 (average of three runs) (b_{30} = vol. of carbon dioxide released in 30 min.). This method of expressing the results was used because the number, not the weight, of larvæ was held constant in each run. The grand average live-weight per larva was 191 mgm. In other runs breis were treated with ethyl alcohol to a final concentration of 33⅓ per cent. No evolution of carbon dioxide was detected, an indication that at this concentration cholinesterase is totally inhibited. Tyrosinase is probably inhibited also, since the alcohol-treated breis showed no darkening. The study of breis inhibited with tetraethyl pyrophosphate is difficult by this method because the hydrolysis of the pyrophosphate causes the evolution of carbon dioxide from sodium bicarbonate. In the only attempt made to use tetraethyl pyrophosphate (at 10^{-3} *M*), however, the rate of evolution of carbon dioxide was unaltered when the acetylcholine was tipped in. The inhibition of all cholinesterases by tetraethyl pyrophosphate was considered too well documented to justify further study.

Using *Tribolium* adults, the b_{30} per gm. live-weight was 132 µl. ± 3·4 (average of three runs). Again, ethyl alcohol, 33⅓ per cent final concentration in brei, gave 100 per cent inhibition. Preliminary experiments had shown that for larvæ as well as pupæ of *Tribolium* the b_{30} was of the order of 60 µl. per gm. live-weight.

These experiments demonstrate the presence of cholinesterase in larvæ of *Tenebrio molitor* and adults, pupæ and larvæ of *Tribolium confusum*.

I am indebted to Dr. B. N. Smallman for advice and encouragement.

Intranuclear Proteins of the Oocytes in *Artemia salina* L.

Recent biochemical and cytological investigations, dealing with the problem of intranuclear proteins, suggest that the nucleus has an important role in protein metabolism. In addition to the nucleoproteins, of both the ribonucleic and deoxyribonucleic types, histones and more complex non-histone proteins have also been described in the nucleus. Chromosomin[1] and the so-called 'residual protein'[2] belong to this last group. But, as earlier suggested by A. L. Dounce[3], it was emphasized by cytological studies of A. W. Pollister and C. Leuchtenberger[4] that the interphase nucleus contains a considerably larger amount of other proteins of non-histone type. Evidence has accumulated that it is mainly these non-histone proteins which differ from cell to cell; this fraction can be important in the general metabolism of the cell.

Young oocytes of *Artemia salina* L. seem to be a favourable material for the cytochemical study of the intranuclear proteins. The nucleoproteins during oogenesis have already been described[5]; a large amount of ribonucleic acid was found in the nucleoli, and strongly Feulgen-positive granules were revealed.

By the use of the Millon reaction, according to the cytochemical technique of A. W. Pollister and collaborators[6,7] (both the trichloroacetic and the sulphuric), on material fixed in various liquids, the presence of two different proteins, one of the histone and another more complex, becomes evident. The results are different if the material is fixed in liquids containing acetic acid.

The Millon reaction for total proteins on material fixed in liquids without acetic acid (alcohol–formol (90–10), formol 30 per cent, osmic acid, formol–calcium (Baker, Helly, Gelei) is strongly positive in nucleoplasm and nucleoli. This nucleoplasmic protein is more easily detectable on oocytes fixed in alcohol–formol, formol 30 per cent and osmic acid than in other non-acetic fixatives, because it is homogeneous in the former while granular in the latter. The intensity of the reaction can be little different from one ovary to another and is probably related to the moment of fixation. By highest intensity, the chromatin granules do not stand sharply out against the Millon-positive homogeneous nucleoplasmic protein mass. Just before the great cytoplasmic increase in the oocyte the reaction is strongest; a decrease occurs in the nuclear vesicle. Some ovaries contain a small number of oocytes which are partially or completely lacking in this nucleoplasmic protein. The Millon reaction (sulphuric), after treatment of the sections to detach most of the histone, was also positive.

Animals fixed in liquid containing acetic acid (Carnoy, alcohol – formol – acetic acid (85–10–5), Zenker) have shown the following results: the Millon reaction for total protein is only positive in nucleoli and chromatin granules, while clearly negative in the nucleoplasm; after extraction of the histone, the Millon reaction is practically negative throughout the nucleus, excepting for the chromatin granules, which are lightly positive.

These results with our *Artemia* material seem to prove the presence of a large amount of protein of non-histone type in addition to histone and the nucleoproteins mentioned above. This protein is only present in material fixed without acetic acid. Thus fixation with acetic acid, not only in alcoholic but also in aqueous medium, involves a loss. Staining reactions demonstrated a strong affinity for acid dyes, like orange *G*.

Both histone and acetic acid-soluble basic protein were present in nucleoli, but only the latter in nucleoplasm, at the stage when the oocyte shows the greatest nucleolar activity as seen by an increase of the basophilia and the number of nucleoli[5]. Thus this non-histone basic protein seems to be the expression of a metabolic activity of the nucleus preparing to function in the synthesis which accompanies growth of the oocyte, as suggested by Pollister[8]. Possibly synthesized in nucleoli, this protein of non-histone type which is soluble in acetic acid should be able to influence the cytoplasmic activity through the nucleoplasm.

Sterility in *Theobroma cacao* L.

POUND[1], during his 1937–38 expedition to the upper reaches of the Amazon, made a collection of *Theobroma cacao* L. types which he hoped would be resistant to witches broom disease, *Marasmius perniciosus* Stahel. These were sent to Trinidad as material for his breeding programme. In 1943 Posnette[2] visited Trinidad from the Gold Coast and obtained pods from these trees, as he was interested in their possible resistance to cacao swollen shoot virus.

With hand-pollination, Posnette soon found that the trees were all self-sterile but to a limited extent cross-fertile. In their cross-fertility they differed from the cultivated Trinidad population, in which all self-sterile trees are also cross-sterile, depending for successful pollination on self-fertile trees. The self-fertile trees in this Trinidad population cross readily among themselves and with the self-sterile trees[3]. No satisfactory genetic hypothesis has been advanced to explain this system.

The progeny of Posnette's crosses were planted at Tafo in 1945. An extensive programme of cross-pollination on the progeny has enabled us to formulate a genetic hypothesis to explain their sterility. In the types so far tested we have found that five alleles (designated *W*1, *W*2, *W*3, *W*4, *W*5) at a single locus are involved. The alleles differ in potency and follow the sequence $1 > 2 = 3 > 4 > 5$. The diploid constitution of the male and female parent determines the success or failure of the cross. The alleles exhibit dominance according to the above sequence.

In two plants which have a similar sterility mechanism, *Crepis foetida*[4] and *Parthenium argentatum*[5], dominance is only exhibited in the pollen; the alleles of the style act independently. In these *T. cacao* types the female reaction, in addition to the male, is sporophytic and dominant, and so the reciprocal-cross differences found in *Crepis* and *Parthenium* cannot occur. The system we have found in *T. cacao* resembles the hypothetical one suggested by Bateman[6].

The cacao types differ further from *Crepis* and *Parthenium* in that the stylar tissue is not the site of the incompatibility. Failure occurs at a much later stage, possibly after fertilization of the ovules. Although the system ensures cross-pollination, it is at enormous expense in terms of reproductive material.

A full report of the genetics of sterility in these types and their relation to the system found in the Trinidad population will be published later. The present communication is published by permission of the Director of Cacao Research.

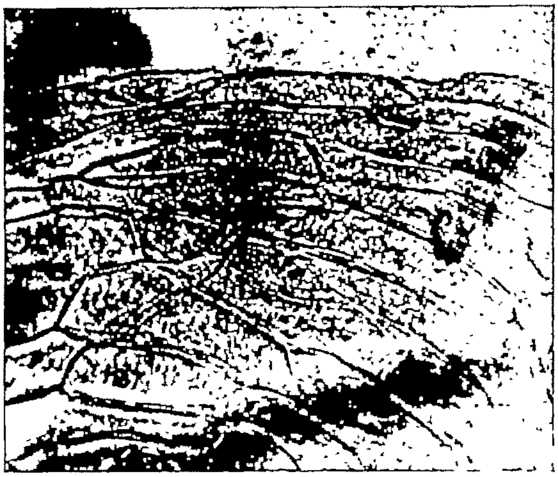
Resistant Components of the Cortex of Animal Hair

THE possibility that there exists beneath the scaly layer or cuticle of animal hair another peripheral layer has been discussed both in these columns[1,2] and elsewhere[3,4]. The supposed layer has been named variously subcutis, between-membrane, and cortical mantle. The most convenient way to show that there does exist a resistant non-keratinous residue beneath the cuticle was described by Alexander and Earland[4]. Hair or wool is oxidized with weak aqueous peracetic acid and then extracted with dilute ammonia solution. The oxidation destroys the disulphide cross-links which stabilize the keratin, rendering it soluble in alkali. The non-keratinous residue consists of (*a*) thin tubes each looking like a cast of the cuticle and consisting mainly of the thin membrane, the epicuticle, which envelops the scales externally, and (*b*) a cortical residue, which seen from the side looks like a rather tenuous tube of cortical cells[4]. This latter was thought to be the new morphological component, the subcutis[4].

In order to make sure of the exact disposition of this residue within the cortex, the experiment has been carried out on cross-sections of oxidized hair. On treatment with ammonia, these cross-sections swelled to about three times their original diameter and the cortical residue was seen to extend network-like throughout the cortex and to consist of the cell membranes which originally bounded the cortical cells. There was no sign of a distinct subcuticular membrane. The material used in this work has been mainly human hair and wool fibres; but the accompanying illustration is of a portion of the cross-section



Portion of a cross-section of oxidized whale hair treated with dilute ammonia. This hair has no cuticle. The keratin has dissolved from the cortical cells leaving the cell membranes and minor resistant particles

of whale hair. This interesting hair was chosen for illustration because it has no cuticle and the cortical cells are very well defined right to the edge of the hair[5].

In addition to the cell membranes, various other particulate forms (or short sections of elongated forms) resist solution. Of these, part are found in nuclear cavities (see illustration) and may be derived from nuclear membranes, and the remainder are distributed throughout the cells. In wool fibres the distribution of these latter particles is asymmetrical. They are found predominantly in one half of each fibre cross-section, and this distribution may be related to various other phenomena, such as twisting[6], curling[7], and dyeing, which point to a structural asymmetry in wool fibres.

I wish to thank Mr. John Facq for a gift of whale hair.

'Slow'- and 'Fast' Nerve Fibres in Locusts

Pringle[1] has demonstrated the existence in the cockroach of a functional double-innervation of the extensor tibialis muscle. He describes a single slow and a single fast fibre to this muscle, both the axons running in the metathoracic nerve trunk designated *3b*. The threshold for excitation of the fast fibre is lower than that of the slow fibre. Single impulses sent down this nerve produce brief twitches in the extensor tibialis. There is incomplete fusion of twitches at 50 impulses per sec. and a smooth tetanus results at frequencies in excess of 70 per sec.

In order to demonstrate the properties of the slow-fibre system, Pringle found it necessary to dry out the whole nerve trunk and then remoisten it with saline carefully. In this way he was able to knock out the fast-fibre system while retaining functional activity in the slow one. Electrical stimulation of the slow fibre then initiates a smooth tonic contraction of the muscle at frequencies of 50 per sec. and above. Electrical records of the muscle potentials produced during slow-fibre stimulation show a marked facilitation. The extent of the facilitation is about six times, taking 0·1 sec. to develop maximal spike height at 185 impulses per sec.

In the locusts *Locusta migratoria migratorioides* R. and F. and *Schistocerca gregaria* Forsk, the probable homologues of Pringle's cockroach nerve *3b* contain only slow fibres to the extensor tibialis muscles. Stimulation of these nerves gives a smooth tonic contraction which starts at about 10 impulses per sec. The speed of contraction increases with increasing frequency of stimulation and is rapid at 200 impulses per sec. Fast fibres to the same muscles are contained in the large crural nerve trunks, the probable homologues of Pringle's nerve *5* in the cockroach. Single impulses in these nerve fibres give powerful twitches. Smooth tetanus begins at about 30 impulses per sec. In the locusts there is no evidence of electrical facilitation in either the fast or the slow systems. Each nerve stimulation gives an 'all-or-nothing' electrical disturbance in the muscle, as recorded by external electrodes.

This anatomical separation of the two types of nerve supplying the same muscle makes it a simple matter to demonstrate the existence of slow- and fast-fibre systems in an insect. The two types of contraction can be shown in the same animal consecutively by placing stimulating electrodes on the appropriate nerve trunks, and applying suitable electrical pulses to each in turn. Very little dissection is required, and the whole is very suitable for class demonstration and experiment. The preparation renders possible a detailed study of the events associated with neuromuscular transmission in the two systems.

Heterothallism in *Chætomium*

During the course of an investigation of the fungus flora of seed oats being carried out by Malone[1], evidence was obtained which suggested that *Chætomium elatum* Kunze and Schmidt might be heterothallic in spite of the fact that Marchal and Marchal[2] and Ames[3] had reported fruiting from single ascospore cultures of this species. To investigate this point, eight single ascospore isolations obtained from a perithecium produced on an oat seed were grown on a wide range of media, where they failed to produce fertile perithecia although perithecial primordia were formed abundantly. Fertile perithecia were obtained, however, in some cases when these isolates were plated in pairs in all combinations and the isolates were therefore numbered 1–8 with 1 arbitrarily designated as (+). Of the eight strains, 1, 5 and 6 were (+) and fruiting occurred when these were plated with the (−) strains 2, 3, 4, 7 and 8. A further 114 single ascospore isolations were made and cultured in quadruplicate against the original 1 (+) and 2 (−) strains. Of these, 63 fruited in contact with a (−) strain and 51 with a (+) strain, thus giving totals of 66 (+) and 56 (−) for the 122 isolates used. Control cultures of all isolations produced only perithecial primordia.

Observations showed that the density of perithecial production was not uniform but depended upon the particular strains brought together. The regularity with which this phenomenon occurred when repeated matings with isolates 1–8 were made over a period of time showed it not to be fortuitous, and suggests that the heterothallism exhibited may be effected by a multiple allelomorphic system affecting the quantitative capacity for sexual reproduction.

Chivers[4], in his monograph on the genus, listed twenty-three synonyms under *Chaetomium globosum* Kunze. Three forms were isolated from seed oats which fell within his diagnosis for the species. Of these, two were very similar morphologically and differed markedly only in the colour of the perithecia, which was in one case greenish and in the other grey. Both these forms produced fertile perithecia from single ascospore cultures. The third form required the pairing of single ascospore cultures for perithecial production; and of fifteen isolates, seven were found to be of one mating type and eight of the other. This third form closely agreed with *Chaetomium olivaceum* Cooke and Ellis[5], which was considered by Chivers[4] to be synonymous with *C. globosum*. The fact that it is heterothallic and has much larger ascospores (12·3 μ × 9·6 μ, as opposed to 10·5 μ × 8·5 μ for the green form and 10·5 μ × 8·0 μ for the grey form) indicates that the synonymy of Chivers cannot be accepted and that the species of Cooke and Ellis should be re-erected. All three forms could be separated physiologically by their differing reactions to different sources of carbon in media employed for this purpose.

This work formed part of an investigation carried out for an honours degree in the Faculty of Agriculture in the Queen's University of Belfast under the direction of Prof. A. E. Muskett, to whom I am indebted for advice and encouragement.

Spores and Tracheids of Vascular Plants from the Vindhyan System, India: the Advent of Vascular Plants

IN a recent paper entitled "Evidence for the Existence of Vascular Land Plants in the Cambrian", by K. Jacob, (Mrs.) Chinna Jacob and R. N. Shrivastava, to be published shortly in *Current Science*, we have recorded a few spores and fragments of tracheids of vascular land plants from authentic samples of the Neobolus Shales of the Salt Range, the Middle and Upper Cambrian of Kashmir and the Cambrian of Spiti. Some of the spores described there are provided with bladders and in others they are absent, the latter in some cases showing body ornamentation. In this preliminary note we have tentatively referred these spores to the Pteridophyta and the Pteridospermæ; it is possible that some may even belong to the primitive Gymnospermæ.

Pursuing these studies further, specimens of the Suket Shales (containing well-preserved specimens of *Fermoria*) belonging to the upper part of the Semri series[1] of the Lower Vindhyans, near Rampura (lat. 24° 28′; long. 75° 26′), Central India (now Madhya Bharat), were treated with hydrofluoric acid followed by Schultze's fluid. The specimens macerated belong to H. C. Jones's original collection[2] from the above locality (Geological Survey of India, Reg. No. K24/997). Several spores and a few fragments of woody elements were recovered. But the spore assemblage is restricted to only five or six types, all of which appear to be comparatively primitive. In one slide as many as twenty spores, with or without tri-radiate mark, were recovered. Winged spores or those with surface ornamentation or furrow were entirely absent.

In view of the prevailing scepticism regarding the advent of vascular plants so early as the Cambrian, all possible precautions were taken against contamination and the results obtained by us were repeatedly checked.

Although A. K. Ghosh and others[3] have reported the occurrence of spores and tracheids in the Cambrian sediments of India, there still persists some doubt regarding their finds. The present communication recording spores obtained from samples of the Suket Shales, together with the results of our examination of Cambrian sediments from the Salt Range, Kashmir and Spiti[3], may, it is hoped, carry conviction that such organic remains, if carefully searched for, will be found to occur in several Cambrian horizons hitherto believed to be devoid of any trace of vascular plants. From the Olive Shales of the Lower Vindhyans in the Mirzapur district, Ghosh and Bose[4] figured four pieces of woody elements and a single small spore. From the Suket Shales we have recovered several more plant remains, including a variety of spores.

In this short communication no attempt is made to describe the individual spores, though it may be stated that those recovered from the Suket Shales have been provisionally grouped into six major types depending on their morphology, and include spores belonging probably to the primitive Pteridospermæ and Pteridophyta (? Psilopsida, ? Sphenopsida), and to doubtful primitive Gymnospermæ.

Conclusions. (i) ***Advent of land plants.*** Ghosh and Bose[4] examined a sample of the Olive Shales (Semri series, Lower Vindhyan), from a locality east of Patwadh, Mirzapur district, Uttar Pradesh, and reported a few fragments of tracheids and several small smooth-walled spherical spores, one of which was figured by them. The spore, which is rather small in size with a short raised ridge or fold on one side, could also possibly be considered to belong to a primitive non-vascular plant. The several spores recovered by us from the Suket Shales (Semri series) belong to at least six different groups of vascular plants, probably representing the Equisetales and other primitive Pteridophyta, the Pteridospermæ and very doubtful primitive Gymnospermæ, in addition to some non-vascular cryptogams. The additional evidence now obtained by us, along with the earlier reports of traces of vascular plants in the Cambrian of the U.S.S.R.[5], Esthonia[6], eastern Sweden[7] and India[2,3,4], should offer food for thought to those who are not inclined to accept the existence of vascular land plants in pre-Silurian times. In view of the poor preservation of the comparatively few spores recovered, however, these tentative suggestions of affinities should be taken with reserve. Nevertheless, it is fairly safe to suggest that the vascular land plants were in existence even as early as the Lower Cambrian.

(ii) *Age of the Lower Vindhyan.* The occurrence of probable Equisetalean spores recalling those described by Naumova[5] from the Lower Cambrian Pre-Baltic clays, and by Reissinger[6] from sediments of more or less the same age in Esthonia, seems to throw additional light on the age of the Lower Vindhyans. In view of the close similarity of the majority of spores from the Suket Shales with those mentioned above, it is suggested that the Suket Shales occupying the top part of the Lower Vindhyan (and possibly the entire Lower Vindhyan, comprising 1,000–3,000 ft. of sediments) may not be older than the Lower Cambrian in age. It is possible that the Upper Vindhyans may then be Upper Cambrian with the possibility of their extension to the Ordovician. In this connexion, a statement by Pascoe[10] on the age of the Vindhyans is of significance: "An assumption that the Lower Vindhyan represents the lower half of the Cambrian would make the Upper Vindhyan equivalent perhaps to the Upper Cambrian *plus* an unknown portion of the succeeding system or systems. This would admittedly fill a gap in the geological sequence, for there are no other sediments in the Indian Peninsula which could with probability represent any part of that sequence from the Cambrian to the Lower Carboniferous. That such a long period of time should be entirely unrepresented over such an extensive area is, of course, possible, though the odds seem slightly more in favour of some relics of the Palæozoic rivers, estuaries or seas surviving".

It is of further interest to note that the spores recovered by us from the Neobolus Shales and other Cambrian sediments from Kashmir and Spiti[9] show a higher morphological evolution than those from the Suket Shales, probably because the spores from the latter belonged to more primitively organized land plants which flourished in earlier Cambrian times. The Neobolus Shales and the early Palæozoic sediments of Kashmir and Spiti, which yielded the more highly organized spores, are probably of ? Middle and Upper Cambrian age. On the whole, it seems not unreasonable, therefore, to refer the Lower Vindhyans to the Lower Cambrian. However, the evidence at present available is still meagre and the above suggestions on the age of the Vindhyans should be taken with reserve.

The discovery of the remains of vascular land plants from the Vindhyans and other Cambrian sediments in India and elsewhere is of far-reaching significance in stratigraphy and in unravelling the early phylogeny of the vascular plants, on which an entirely new light is now being thrown, necessitating a re-orientation of certain well-established ideas. It is therefore of prime importance to undertake careful and systematic search for the remains of vascular plants in the early Palæozoic and even in the Proterozoic sediments.

Taxonomy of Green Bacteria

IN the past, various small organisms have been described as 'Green Bacteria', but for the most part too inaccurately to be sure of their identity. In 1906, however, Nadson[1] (cf. also ref. 2) gave the name *Chlorobium limicola* to a microaerophilic, chlorophyll-containing organism of bacterial dimensions which shares the habitats of Purple Bacteria, and which has been studied in pure culture by van Niel[3]. Lauterborn[4] proposed the family Chlorobacteriaceæ for a group of similar organisms which, when in a mass, appear yellow-green.

Morphological studies caused Geitler and Pascher[5] to include in the Cyanochloridinæ = Chlorobacteriaceæ a considerable number of species which they described in an appendix to the Cyanophyceæ (cf. also ref. 6). Among these there are yellow-green as well as blue-green forms. Since some Cyanophyceæ are always yellowish, and many others, under unfavourable conditions, fade to a similar hue, it is impossible to decide without culture experiments where these bacteroid forms belong.

In such experiments a number of these forms, isolated from mud, proved to be blue-green, to contain chlorophyll *a* (no *b*), and to produce oxygen bubbles when exposed to strong illumination. Such organisms are evidently true, though very small, Cyanophyceæ, whereas others, growing only after the oxygen has been consumed by other bacteria, are greenish-yellow viewed against the light, but dark bluish-green in incident light. They contain a green pigment, identical with the bacteriochlorophyll of Purple Bacteria. This was confirmed with the help of a pure culture of *Chlorobium thiosulfatophilum*, made by Dr. H. Larsen in van Niel's laboratory at the Johns Hopkins Marine Station, and kindly sent to us.

Other pigments previously isolated from similar organisms were products of decomposition. Comparison of the absorption spectra of the living cells with those of their pigments in solution and isolated by sugar chromatography prevents this error.

Our result shows that the relation of the "Green Sulfur Bacteria", as they are called by van Niel, to the Purple and Brown Bacteria, is still nearer than he believed. I propose to call all these together 'Chlorobacteriales' because they have the bacteriochlorophyll in common.

The pigment analyses were carried out in the Botany Department of the University of Heidelberg under the supervision of Prof. A. Seybold, to whom I am grateful for his collaboration.

Deposition of a Coarse Aerosol released from a Low-flying Aircraft

Experiments are being carried out in East Africa to investigate the behaviour of coarse aerosols released from low-flying aircraft. Such aerosols, the droplets of which have diameters covering approximately the range 5–200 microns, are much used in an *ad hoc* fashion to control insect pests; but little is known of the effect upon their behaviour of variations in meteorological and other field conditions.

Aerosol behaviour is complex under field conditions, and the number of variables must be limited if ordered knowledge is to be obtained. It is difficult enough to treat mathematically gaseous diffusion in the atmosphere when the source is relatively non-turbulent; when the problem is complicated by sedimentation effects and the presence of a very turbulent source such as an aircraft's slipstream, and also by variations in surface vegetation and ground contour, any investigation must of necessity be mainly empirical.

As a preliminary basis to our work, we have investigated in open country the form of the ground deposit of an aerosol released from a low-flying aircraft flying across the wind. We have used a constant aircraft height of 30 ft., a constant drop spectrum, and only one solution. The aerosol was produced from a boom-and-nozzle apparatus fitted to an Anson aircraft, had droplets varying from 5 microns to 250 microns approximately, and had a mass median diameter of 70–80 microns. The solution was a 10 per cent w/v solution of technical DDT (80 per cent *pp'* isomer of DDT) in a solvent consisting of 1 part of Shell 'Power Kerosene' to 1 part of Shell 'Diesoline'.

The degree of atmospheric turbulence was measured by a parameter deduced by Deacon (unpublished) as an effective and measurable replacement for the Richardson's number. We have used it in the form:

$$F = \left\{\frac{T_{10} - T_{2\cdot 5} + \Gamma . \delta h}{(u_5)^2}\right\},$$

where T_{10}, $T_{2\cdot 5}$ are the air temperatures (in deg. F.) at heights of 10 m. and 2·5 m., respectively, u_5 is the mean wind speed (in ft. per sec.) at a height of 5 m., and $\Gamma . \delta h$ is the numerical value of the dry adiabatic lapse over an interval of 7·5 m. Thus F is positive for inversions, zero for dry abiabatic lapse-rates, and negative for super-adiabatic lapse-rates.

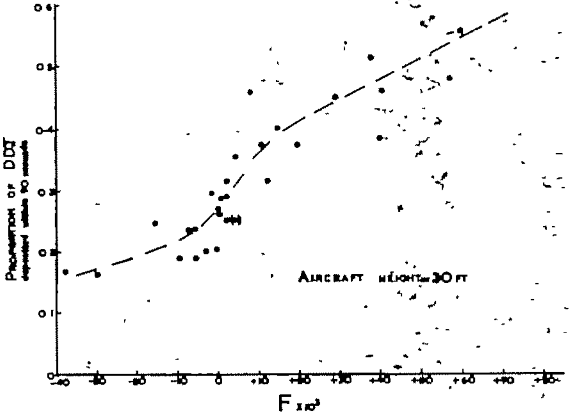

Fig. 1. Proportion of DDT deposited within an interval of 90 sec., for various values of *F*, the measure of the degree of atmospheric turbulence

Ground deposits were measured in two ways: by size-counts upon glass plates coated with magnesium oxide, and by colorimetric estimations of a fast dye added to the solution. Actual volumes of deposits were obtained from the size-counts, whereas the colorimetric method gave equivalent dosages of DDT, or of volume of original solution. Some measure of losses of solvent by evaporation was therefore possible.

The deposit of DDT, expressed as a proportion of the amount emitted from the aircraft, was summed for various values of the ratio (distance downwind)/(mean wind speed at 5 m.). This ratio gives an approximate measure of the time-interval elapsing between production of the droplets and their deposition at a sampling point. The variation of this proportion with changes in *F*, the measure of atmospheric turbulence, is shown in Fig. 1; a time interval of 90 sec. has been considered. It is evident that the aerosol is deposited more readily during inversions than during conditions of super-adiabatic lapse-rate.

The various experiments were grouped according to their values of *F*, and for each group the average values of the proportion deposited were calculated

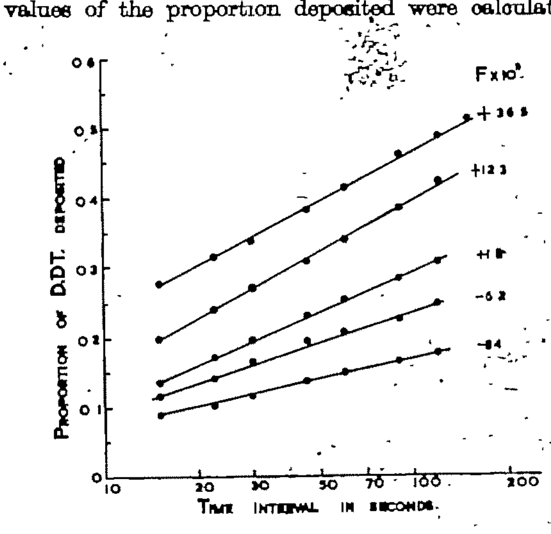

Fig. 2. Variation with time-interval of the proportion of DDT deposited upon the ground, for different degrees of atmospheric turbulence

for various time-intervals. The results are shown in Fig. 2, where time-intervals are recorded on a logarithmic scale. The graphs show that the total deposit increases most rapidly with time during inversions.

Comparison of results from the two methods of assessment showed that deposits collected beneath the aircraft track had solution strengths which were approximately double that of the original solution, that is, 50 per cent of the solvent had been lost during the very few seconds required for these deposits to form. A correlation test showed that the loss of solvent increased significantly with time-interval, but so slowly that after 3–4 min. the losses had only increased to 60 per cent. It seems probable that the kerosene evaporates very rapidly during the first few seconds after the droplets have been formed, leaving droplets composed of relatively involatile substances.

The results suggest that a simple, practicable relationship can be found between aerosol behaviour and simple meteorological measurements. The exact form of the behaviour of an aerosol will depend greatly upon the sizes of its constituent droplets, and our results are being analysed to discover how droplets of various sizes are deposited. A preliminary study suggests that the smaller the droplet the greater is the effect of a change in the degree of atmospheric turbulence, as would be expected. Experiments are also being carried out with different heights of the aircraft, and over areas of woodland.

A fuller account of this work is to be published elsewhere.

Longitudinal Elastic Waves in Cylindrical Rods

Although Pochhammer's[1] well-known solution for elastic waves in cylindrical rods has been in existence for many years, two problems arising out of it in connexion with longitudinal motion have yet to be solved.

The first difficulty relates to the physical significance of the higher modes (as opposed to their theoretical importance, which has been explained by Cooper[2]). The transmission of a pulse in one of the higher modes would be evidenced by very high phase velocities for long waves and, in the course of carefully planned experiments with a pressure bar, Davies[3] did not detect such an effect (see, however, Morse[4], who describes experiments with rectangular rods). An explanation of this fact would be reassuring, since engineering theories of longitudinal waves do not give rise to higher modes[5].

The second problem is that pointed out by Love[6], and concerns a free end of the cylinder where reflexion occurs. The stresses of Pochhammer's solution may be written in the form:

$$\begin{aligned} \mathbf{xx} &= (\text{real function of } r) \exp\{i\,\xi\,(x - ct)\} \\ \mathbf{xr} &= (\text{imaginary function of } r) \exp\{i\,\xi\,(x - ct)\} \end{aligned} \qquad (1)$$

for any particular wave number ξ and phase propagation speed c. Thus, if the normal stress $\mathbf{xx}$ is always to vanish at a free end, $\mathbf{xr}$ will not do so.

This problem may be regarded as if perfect reflexion occurs with the superimposed effects of an *applied* stress system:

$$\mathbf{xx} = 0\,;\quad \mathbf{xr} = (\text{function of } r) \exp(i\,\xi\,ct) \qquad (2)$$

at the hitherto free end. Now the question arises: Is the effect of the auxiliary system (2) local, or does it, in some way, distort the retreating reflected wave? It is, perhaps, to be expected that the effect is local since steady longitudinal vibrations of a rod might not otherwise be possible; but it would be virtually impossible to find the answer by direct experiment.

Pochhammer's results are reached if the trial solution:

$$u_x = f_1(r) \exp\{i\,\xi\,(x - ct)\}\,;\quad u_r = f_2(r) \exp\{i\,\xi\,(x - ct)\};\quad u_\theta = 0 \qquad (3)$$

is used in the general equations of motion. If equations (3) embrace the most general longitudinal wave and they inevitably lead to equations (1), it is apparent that a motion giving (2) is not possible. This is obviously so if, in fact, the only physically realized mode of Pochhammer's solution is the first.

What is the alternative if displacements due to system (2) are not propagated? Since the applied force always has zero resultant, the problem is analogous to those involving an appeal to St. Venant's principle, the disturbance now being time-dependent. It has been shown by Goodier[7] that the effects would be local in the static case as a simple consequence of the conservation of energy. In the absence of wave transmission, this would still be true for dynamical cases. Thus a harmonic wave approaching a free end would suffer complete reflexion. But its form would become temporarily blurred near the stress-free section.

These views are advanced as a suggestion rather than as a proof. They are offered because it appears to me that this is not the only vibration problem the exact solution of which could be completed by the establishment of some form of dynamical St. Venant principle; for example, certain plate problems seem to fall into this category.

Elastic Deformation and the Laws of Friction

It has been shown by Bowden and his co-workers[1] that the classical law of friction $F = \mu W$ is dependent on plastic deformation of the asperities in contact on the rubbing surfaces. In the case of high polymers, however, Lincoln[2] has shown that, ideally, relationships of the form $F = kW^{2/3}$ are to be expected at small loads, as a result of elastic deformation of the asperities. Other examples of high polymer friction[3], and particularly the friction of textile fibres[4,5], indicate similar relationships although, in the case

RELATION BETWEEN FRICTIONAL FORCE AND LOAD IN TEXTILE FIBRES

Material	Value of index n in $F = kW^n$	Reported by
Fibro rayon	0·75–1·0	Guthrie and Oliver (ref. 4)
Cellulose acetate	0·96	Howell (ref. 5)
Viscose rayon	0·91	
Undrawn nylon	0·90	
Drawn nylon	0·80	

of textile fibres, of a more general form $F = kW^n$, where n may lie between 0·67 and unity (see table).

It is commonly supposed that if a law of the type $F = kW^n$ is obtained, then as the value of n approaches unity so also the deformation of the asperities must approach more closely a state of full plasticity, so that when $n = 1$ the deformation is entirely plastic and Amontons's laws are valid. The assumption that $n > 0·67$ indicates that some degree of plastic deformation may, however, be unjustified, and may lead to an inaccurate concept of the deformation process actually occurring. In general, if N asperities are involved in the frictional process, the frictional relationship would be of the form $F = \sum_{1}^{N} C_i W_i^{2/3}$, which does not imply $F = kW^{2/3}$ except in special circumstances. For example, if contact between two cylindrical fibres, possessing longitudinal fluted asperities of uniform cylindrical cross-section and being uniformly distributed, is considered, it is possible, using Hertz's classical formulæ[6], to show that the relationship between frictional force F and load W is:

$$F = SW^{8/9}\, R_0^{2/9}\, R_a^{2/9}\, K/d^{1/3}, \qquad (1)$$

where S is the effective shear strength at the interface in the real area of contact, R_0 the radius of the fibres, R_a that of the asperities and d their distance apart, and K a constant which includes the Young's modulus of the materials to the power $- 8/9$. A similar relationship is obtained for the friction between a hemispherical specimen (with spherical asperities) and an ideally plane surface. Thus, although the deformation of the asperities was postulated initially as being completely elastic and conforming to the Hertzian power law, the gross frictional force F is proportional to $W^{8/9}$, a result which, if obtained experimentally, might be assumed to indicate that the deformation of the asperities is partly plastic. Equation (1) also illustrates the dependence of the frictional properties on the surface configuration of the rubbing elements—another non-classical feature of the friction of high polymers which has been discussed by me elsewhere[2]. It is only possible, therefore, to decide between plastic and elastic deformation of surface asperities when their dimensions and distribution are known.

A full account of this theoretical treatment will be published elsewhere in due course.

Cleavage Fracture of Zinc Single Crystals

FRACTURE by cleavage across the crystals of a polycrystalline metal is typical of many examples of brittle fracture. The cleavage plane is crystallographic and is observed always to be one of a very limited number of planes irrespective of the orientation of the crystal with respect to the applied stress. In zinc it is likely that the cleavage plane is always (0001), although the crystal may twin before it fractures[1].

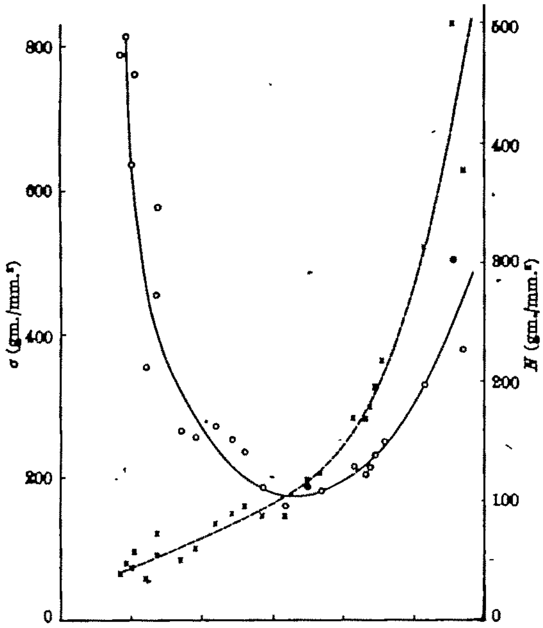
The stress conditions necessary to cause cleavage fracture are not well established, although it has generally been assumed that fracture occurs when the resolved component of the applied stress perpendicular to the most favourably orientated cleavage plane exceeds a critical value. This is known as Sohncke's law, and was formulated following experiments on the fracture of single crystals of sodium chloride. Later work, largely by Schmid and his co-workers, led to the belief that the law was also obeyed for cleavage fractures in bismuth, tellurium, zinc and antimony. This work, and also other work on ionic crystals, has been summarized by Schmid and Boas[2]. Since 1930, little attention has been given to the problem.

Closer examination of the results of Schmid *et al.* raises some doubt as to the general validity of the normal stress law. While some of the results, notably those for bismuth, confirm the law very well, others are not in such good agreement. For zinc, Schmid[3] only obtained results for crystals for which the angle χ between the direction of applied tensile stress and the cleavage plane lay in the range 12–50°; even here the agreement was not very good. Therefore, before proceeding with an investigation of the factors influencing the cleavage strength of zinc single crystals, we felt it advisable to determine whether the stress normal to the cleavage plane was the criterion for fracture.

The zinc used was of 99·99 per cent purity, the main impurities being lead 0·002 per cent, cadmium 0·0015 per cent, copper 0·001 per cent and iron 0·0015 per cent. Single crystals, 6 mm. diameter and 18 cm. long, were grown in argon using the Andrade and Roscoe technique. The moulds employed were of precision-bore glass tubing coated internally with graphite. It was possible to remove the crystals from the moulds without straining them, and care was taken throughout other handling operations to avoid any accidental strains. The crystals were then broken in liquid nitrogen (− 196° C.) using a tensile testing machine in which the stress was applied as near axially as possible. The crystals deformed plastically before fracture, and all results have been referred to the final dimensions and orientations of the crystals.

The graph shows the applied tensile stress, σ, and the resolved component of the stress perpendicular to the cleavage plane, N, at fracture, in each case plotted against χ. Results for crystals for which $\chi < 12°$ have not been plotted, since these did not fracture across the basal plane of the original crystal. It is clear that the stress normal to the cleavage plane is far from constant at fracture.

It seems most unlikely that any non-axial loading would cause such a regular variation of N with χ. However, it is possible that N is affected by the plastic deformation before fracture, which increased from about 1 per cent glide strain when χ approached 90° to about 40 per cent when χ was as low as 15°. An initial very rapid fall of N with glide strain



—○—, Tensile stress parallel to axis of crystal at fracture; – – × – –, tensile stress normal to cleavage plane at fracture

followed by a slower rate of decrease would explain our results if a critical normal stress law applied to completely brittle fractures. It is not easy to test this hypothesis in the important range of plastic strain between 0 and 5 per cent, but our results show that varying the glide strain between 10 and 140 per cent at room temperature, before fracture at − 196° C., does not decrease *N*. It must not be forgotten, however, that Schmid's work, on which the normal stress law is partly based, was on crystals which deformed before fracture, and from this point of view the results are directly comparable.

Although no success has yet been obtained in finding an alternative criterion for cleavage fracture, these results make it clear that it is not always one of a critical stress normal to the cleavage plane.

Structure of Selenium Tetrafluoride

Selenium tetrafluoride was first described in 1907[1], but the compound does not seem to have been obtained pure until quite recently[2]. It is not a particularly easy substance to handle, since it rapidly attacks tap-grease and also reacts slowly with 'Pyrex' glass, forming crystalline selenium dioxide and gaseous silicon tetrafluoride with a trace of boron trifluoride. It is also hydrolysed instantaneously by water or moist air to the dioxide.

I have been studying the structure of this compound by the method of electron diffraction. The first set of diffraction photographs taken showed a pattern closely resembling that described for silicon tetrafluoride and was therefore rejected. A second sample was treated in the following manner. The sample holder was allowed to stand in contact with selenium tetrafluoride vapour overnight and then pumped out before the sample was distilled into it. The freshly distilled material was allowed to stream into the electron diffraction camera for some time before photographs were taken, so that any silicon tetrafluoride present should have been pumped off.

The second set of photographs gave a consistently different pattern from the first set, and this pattern was considered to be caused by substantially pure selenium tetrafluoride. Six maxima were observed extending to $s = 23$ A.$^{-1}$. A radial distribution curve gave a large peak at 1·76 A. and a much smaller, unsymmetrical peak at about 3·0 A. The first peak presumably corresponds to the Se—F distance (about 1·7 A. in SeF_6), which contributes 72 per cent of the total scattering, and the second to the F...F distance or distances, which contribute the remaining 28 per cent of the scattering. If the fluorine atoms were arranged in a regular tetrahedron with Se—F 1·76 A., the second peak should be at 2·87 A.

Scattered intensity curves were calculated for ten models in the usual way. In eight of these models, all four Se—F distances were assumed to be equal and the fluorine atoms were arranged in various possible ways, including a square, a regular tetrahedron and a variety of distorted tetrahedra. Two further models were tried in which two of the Se—F distances were assumed to be longer than the other two. Only one model was found to give completely satisfactory agreement with the visually estimated ring intensities. This model has a distorted tetrahedron of fluorine atoms around the selenium atom with two opposite FSeF angles of 120° and the remaining four FSeF angles equal to 104·5°. The scaled Se—F distance from this model is 1·765 ± 0·025 A., and the uncertainty in the angles ± 10°.

The best model has C_{2v} symmetry, which is consistent with some unpublished results obtained by J. A. Rolfe and L. A. Woodward from the Raman spectrum of the liquid. Only two other Group VI tetrahalides have been studied previously by electron diffraction. In the case of selenium tetrachloride[3] the structure was not determined, and in any event the compound was probably decomposed into a lower chloride and chlorine in the vapour state[4]. The structure of tellurium tetrachloride was found by Stevenson and Schomaker[5] to be a distorted tetrahedron with the majority of the ClTeCl angles equal to 93° ± 3°.

I am indebted to Dr. P. L. Robinson for supplying samples of selenium tetrafluoride, to Mr. J. A. Rolfe for distilling these, to Dr. L. A. Woodward for helpful discussions and to the Department of Scientific and Industrial Research for a maintenance grant.

FORTHCOMING EVENTS

Sunday, July 26—Friday, July 31

Second International Congress on Rheology (in the Music Room, Holywell Street, Oxford).

Monday, July 27

At 11 a.m.—Sir Geoffrey Taylor, F.R.S.: "Rheology for Mathematicians" (Presidential Address).

Tuesday, July 28

Nutrition Society (at the National Institute for Research in Dairying, Shinfield, Reading), at 11.15 a.m.—Scientific Papers and Demonstrations.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

University Lecturer or University Demonstrator in the Faculty of Engineering, to teach primarily in thermodynamics and mechanical engineering—The Appointments Committee, Engineering Laboratory, University of Cambridge, Cambridge (July 31).

Assistant Lecturer in the Department of Economic Science—The Registrar, The University, Liverpool (August 1).

Chemist, male (with first- or second-class honours degree in chemistry), in the Fuels and Lubricants Section, Central Laboratory, Chiswick—The Staff Officer (F/EV.241), London Transport, 55 Broadway, London, S.W.1 (August 1).

Deputy Senior Chemist (with honours degree or equivalent, and at least five years experience in the gas or chemical industries) for analytical and investigational work, and the supervision of such work—Industrial Relations Officer, West Midlands Gas Board, 6 Augustus Road, Edgbaston, Birmingham 15 (August 1).

Lecturer in Agricultural Chemistry and a Lecturer in Agricultural Biology (with agricultural degree, or equivalent degree in the appropriate science)—The Secretary, Shuttleworth College, Old Warden Park, Biggleswade, Beds (August 1).

Plant Physiologist (with sound fundamental training, together with research experience) for studies on the physiology and metabolism of fruit under storage conditions in relation to orchard factors—The Secretary, East Malling Research Station, Maidstone, Kent (August 1).

Research Assistant (with honours degree in chemistry)—The Registrar, College of Technology, Suffolk Street, Birmingham 1 (August 1).

Assistant Lecturer in Mathematics (Pure or Applied)—The Principal, Royal Holloway College, Englefield Green, Surrey (August 6).

Assistant Physicist (with good honours degree in physics) at the Hogarth Radiotherapeutic Centre—The Secretary, Nottingham General Hospital, Nottingham (August 8).

Lecturer (with first- or second-class honours degree in mechanical engineering, and preferably with knowledge of one or more of the following subjects: (*a*) materials and structures, (*b*) fluid mechanisms, including supersonics, (*c*) ballistics, (*d*) servomechanisms) in the Department of Applied Mechanics—The Director of Studies, Royal Naval College, Greenwich, London, S.E.10 (August 8).

Lecturer in Mathematical Physics—The Secretary, The University, Edinburgh (August 8).

Assistant Statistician (Assistant Experimental Officer grade) (with pass degree or equivalent qualification, and preferably with knowledge of both mathematics and horticulture, or botany) for the examination and analysis of experimental data—The Secretary, East Malling Research Station, Maidstone, Kent (August 14).

Experimental Officer (H.N.C. or better in physics, and preferably with research experience, including electronics experience) in the D.S.I.R., Food Investigation Torry Research Station, Aberdeen, to work on general physical problems relating to fish—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.116/52/A (August 14).

Assistant Lecturer in Botany (with special reference to either cytology, genetics or ecology)—The Registrar, The University, Nottingham (August 15).

Assistant Lecturer in Geography at Makerere College, Uganda—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (August 15).

Lecturer (qualified either in Science (physical or biological) or Mathematics, and with teaching experience) in the Department of Education—The Registrar, University College of Wales, Aberystwyth (August 15).

Lecturer in Physiology—The Registrar, King's College, Strand, London, W.C.2 (August 15).

Electronic Engineers or Physicists, Principal Scientific Officer grade (with first- or second-class honours degree, or corporate members of the Institution of Civil or Mechanical or Electrical Engineers, or with evidence of outstanding ability) in the Royal Naval Scientific Service, Gloucestershire, to take charge of teams responsible for design of large-scale equipment and its development to prototype stage—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4336/53 (August 20).

Chemical Engineer (Principal Scientific Officer or Senior Scientific Officer) (with first- or second-class honours degree, or good postgraduate diploma in chemical engineering) at the Atomic Weapons Research Establishment, Aldermaston, to lead team engaged in chemical engineering research, and development of plant and equipment concerned with radioactive materials—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.335/53A (August 22).

Scientist (Grade II), a Scientist (Grade III) or Scientific Technical Officer (Grade I) (with degrees or equivalent in physics, chemistry, mathematics, or mining engineering) on the staff of the Director of Scientific Control in the East Midlands (Nottingham) Division of the National Coal Board, to carry out environmental studies at collieries in connexion with a long-term field research into the occurrence and causes of pneumoconiosis—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/655 (August 24).

Lecturer in Zoology at the Auckland University College, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 31).

Assistant Lecturer in Physiology in the School of Pharmacy—The Secretary, Royal Technical College, Glasgow.

Assistant Meteorologist (with H.S.C. or equivalent in mathematics and physics, and forecasting experience or training) with the Mauritius Government—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M3B/33530/TA.

British Rubber Producers' Research Fellow (with good honours degree in engineering or physics, and industrial or research experience) for research into the mechanical properties of rubber—The Registrar, The University, Nottingham.

Electrical or Mechanical Engineer (Senior Scientific Officer) (with first- or second-class honours degree or equivalent in electrical or mechanical engineering, and at least three years postgraduate research experience) in the Ministry of Supply Design Establishment, Sevenoaks, Kent, to lead section engaged in design and development of electrical and mechanical components and of complete control schemes for armament equipments—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting D.285/53A.

Physical Metallurgist (with postgraduate experience and preferably with knowledge of industrial techniques); a Physical Chemist (with postgraduate experience) to carry on research in some applied field of chemistry and to supervise junior research staff; a Chemist (with postgraduate experience in textiles) for short-term development work in physical testing, and an Honours Chemistry Graduate to carry out the investigation of biochemical problems associated with the food industries—The Director, Ontario Research Foundation, 43 Queen's Park, Toronto 5, Ontario, Canada.

Research Assistant for Microbiological and Biochemical Aspects of Work on Megaloblastic Anaemias—The Registrar, King's College, Newcastle-upon-Tyne.

Research Fellow, Junior or Senior (graduate with biophysical or physiological experience and interest in cerebral dynamics) in the Department of Mental Health—Prof. Millar, The University, Aberdeen.

Research Fellow or Research Student (preferably with knowledge of electronics) in the Department of Physics, for fundamental investigations of either semiconductors or ferromagnetic materials—The Registrar, The University, Nottingham.

Research Fellow in Science—The Secretary, The University of Durham, 38 North Bailey, Durham.

Scientific Officers (with first- or second-class honours degree or equivalent in physics, mathematics or engineering) for operational research on wide variety of problems, under the direction of the Scientific Adviser to the Air Ministry, in London and the provinces—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.285/52A.

Wool Textile Research Council Scholarship in Organic Chemistry—The Principal, Technical College, Bradford.

FREEDOM OF THE UNIVERSITIES OF GREAT BRITAIN

THE report of the University Grants Committee on "University Development 1947 to 1952", which is summarized elsewhere in this issue (p. 180), covers a period of great expansion, both in the size and in the cost of the universities of Great Britain, and while reasons are given for believing that 'no further increase in the number of students is probable or advisable during the coming quinquennium, the report is equally clear in its evidence that the rise in costs is likely to continue. On the financial side, the outstanding feature of the review is the picture it gives of the increasing dependence of the universities on government support and of the extent to which the rising expenditure of the universities is determined by factors, such as increased prices and wages and salaries, which are largely outside their control. Any attempt to hold university expenditure at its present level must force the universities to curtail their existing activities, either by interrupting developments or by reducing admissions, or both.

The dependence of the universities upon State aid is, in fact, likely to grow rather than to diminish, and in discussing this dependence and its reconciliation with the maintenance of academic autonomy, the University Grants Committee points out that there are other factors making for the continued increase in expenditure. The relatively low average age of academic staffs, for example, after a period of intensive recruitment, which brought the total up to nearly 9,000 (as compared with the 10,000 which it was estimated would be necessary) in place of the pre-war 4,000, and a staff/student radio of 1 : 8 instead of the pre-war 1 : 10, means that it will be some time before the full financial effects are felt of such increases in staff. Moreover, the growth of scientific knowledge, depending in turn on greater specialization, increasing numbers of workers, and increasingly costly apparatus and equipment, is likely to be a continuing cause of increased expense which, from the national point of view, cannot be regarded as optimal. The period of consolidation, which the Committee regards as likely to characterize the present quinquennium, holds no hope of a decrease in university expenditure. On the contrary, a continued increase is likely to be demanded in the national interest, and for this the University Grants Committee can see no alternative to an increasing Treasury recurrent grant.

This position is regarded with some anxiety. There is no suggestion in this report that any pressure has ever been put upon the universities in Great Britain by the Government. Successive Governments have repeatedly expressed their recognition of the desirability of preserving the autonomy of the universities; nor did the Select Committee on Estimates, in its examination of the work of the University Grants Committee during the 1951–52 Session, find any evidence that this autonomy was endangered, though it did point to the desirability of some closer control over the spending of the non-recurrent grant and of somewhat fuller information being supplied regarding its expenditure. For the rest, the Select Committee was content to remark that the increasing dependence of the universities upon public money and the absence of direct Parliamentary control over the way the grant is spent involve a correspondingly increased responsibility on the part of each university to ensure that its affairs are managed with due economy and in the best interests of the nation.

That much is fully recognized by the University Grants Committee, which, however, points out that its financial responsibility to the Government contains a latent contradiction to its trusteeship to the universities as guardian of academic liberty; and this success in the discharge of both functions is a tribute to the forbearance of both parties. The universities have recognized that the Committee's responsibilities to the tax-payer prevent it from supporting all the developments that may be academically desirable, while the Government has recognized that the importance of academic independence justifies a freedom from control that would not ordinarily be allowed to bodies so largely financed from public funds.

The University Grants Committee professes to be confident that the partnership and forbearance already developed will continue. The universities, it thinks, fully recognize they have a special obligation to observe strict economy in the expenditure of such public monies, and that the continuance of their present financial privileges is dependent on the continued exercise on their part of a strong and evident sense of financial responsibility, which the quinquennial system itself fosters. Moreover, while without the State the universities cannot obtain sufficient funds to enable them to do their work, without the universities there would be no way of meeting the need for men and women adequately trained to advance knowledge and to hold positions of responsibility in government, industry and the professions.

That this mutual dependence is fully realized on both sides is the chief reason for the confidence of the University Grants Committee for the future, and the direct danger to university autonomy is probably slight. The danger of indirect government guidance of academic policy is, however, much more serious. The interdependence of government and universities is now so firm that no purely administrative device, such as the University Grants Committee or the quinquennial grant, can by itself secure the independence of the universities. The continuance of academic autonomy depends not simply on the degree of good sense and moderation displayed by the universities: it depends above all on the extent to which public opinion understands the reasons why academic autonomy is important and is willing that such autonomy should continue.

The University Grants Committee itself is clear enough that the universities may be called upon to resist sectional clamour. A situation could easily arise, it points out, in which the universities could only meet the demands made upon them by distorting the balance of their work and neglecting studies or teaching which may really be of greater importance, though lacking at that time the advocacy of those with particular interests. The balance of university activity which is desirable in the long-term interests of the community as a whole will not necessarily, or even probably, be the same as that which would result from an uncritical acceptance of all such demands.

There is a special reason for welcoming, at this particular juncture, the unequivocal declaration in this report that, in deciding whether a particular activity should be undertaken by a university, and if so on what scale, the last word should continue to be that of the university itself. Within the past few weeks, a document has been issued by a major political party setting out a programme which includes a proposal on which it is difficult to place any other interpretation than that universities are to be told by the Government of the day what they are to teach. There may be occasions, as the Select Committee on Estimates observed, when the universities themselves may not be in a position to be the best judges of what studies most need to be developed in the national interest. Such occasions can at least be met through the University Grants Committee, even though the device of the ear-marked grant has been explicitly discontinued. To determine the content of academic studies at the behest of a political party or any other external body is another matter, and in resisting such pretensions the universities and the University Grants Committee should have the support of all who are concerned to uphold the high standards and ideals which have won for the universities of Great Britain and the University Grants Committee the respect of the free world.

It is clear from this report that the University Grants Committee itself is not satisfied that the curricula of the universities or the organization of teaching take full account of the changes in the economic and social background of the student of to-day. It is also clear that the universities themselves are already examining the situation, and that the University Grants Committee is fully alive to the implications of the situation. To suggest, however, that the teaching at the universities should take account of changes in our way of life and the community's needs and in that context to advocate appointment of a Royal Commission can only mean that politicians are to be invited to teach the universities their business. The consequences to education and to science of such procedure are writ large in the history of universities in Germany and elsewhere during the inter-war years.

That, however, is not the sole reason for concern at the possibility of indirect influence upon university policy or for welcoming a much more vigorous campaign to secure public understanding of the work and function of the universities in Britain to-day. "University Development 1947–1952" was in the press when the political manifesto already mentioned was issued; but it supplies a complete and dignified answer to the suggestion that the universities are stagnant and out of touch with the needs of to-day. The consolidation of the advances of the past five years, which the universities have recognized as the main task of the present quinquennium, is over much of the field not stagnation. Within the existing general pattern, there is much scope for development and experimentation, and the University Grants Committee notes the persistence within the universities of the mood of criticism and self-examination on which it commented in its last report. Universities, it adds, cannot remain static if they are not to lose their vitality; and while the attitude of the universities to new demands will be determined by their view of their functions, this concept must itself be kept flexible and responsive to the needs of a new age.

Even in Great Britain, the functions of all university institutions are not the same. The universities and university colleges of Great Britain include institutions of a wide variety of types, ranging from the old universities to the smaller foundations which came into being within the past generation. Some of them are consciously experimenting in order better to fulfil what they regard as their proper functions. The report mentions specifically the declared aim of the new University College of North Staffordshire to offer a new type of curriculum, in which the first year of the degree course is "designed as a whole to give an understanding of the heritage of Western civilization, of modern society, and of the nature, methods and influence of the experimental sciences". The University Grants Committee regards a readiness to experiment as important for the development of university policy; and, at a time when there is a pronounced disposition in some quarters to stamp uniformity on the field of education, it has done well to direct attention to the importance of such diversity.

Except perhaps in relation to its bearing on academic staff, the University Grants Committee does not discuss either the teaching or the research function of the university at such length as in earlier reports. Yet the broader purposes of a university education, it points out, were never more important than they are to-day. "Society requires of the university graduate much more than his degree or his expert knowledge of a particular field. It also requires the breadth of outlook necessary for those who are to fill positions of responsibility, and a university cannot be said to have risen to the height of its obligations until it has so designed its teaching as to ensure for all its students who use their opportunities the chance to become, in words spoken by J. S. Mill more than eighty years ago, 'capable and cultivated human beings'."

Both research and teaching incur some dangers through specialization and departmentalism, and it is clear that the University Grants Committee is fully alive to the dangers of fragmentation. While it thinks there is little danger of sponsored research distorting the balance of work in British universities, it deprecates the multiplication of fields of study in the universities without prior consideration of the alternative of development in a specialized research institute. Moreover, the increase in the number of university professors since the Second World War has been due less to the increase in student numbers than to the growth in the volume of new knowledge; and because pursuit of new knowledge becomes increasingly more costly—not only on account of the larger academic staff required, but also because apparatus becomes more elaborate and the size and cost of libraries continually rise—the universities can only maintain their part in the pursuit of new knowledge by increasing dependence on the State.

This latter note is struck more insistently and repeatedly in relation to the distribution of students and the demands of particular fields of study. While the University Grants Committee takes a reasoned view that the total number of university students in Britain is likely to remain relatively stable for some years to come, and even that no increase is likely to be possible without some fall in quality—at least until the increased birth-rate of the latter part of the War begins to take effect—it does not exclude the desirability of changes in distribution between the faculties. Indeed, it suggests that there will be a tendency for the proportion of students of science and technology to grow at the expense of the proportion of arts students, and that such a tendency is desirable in the national interest and should be encouraged.

More, however, is involved than a mere transfer of numbers, and it is here that the University Grants Committee gives repeated warning and that the danger of indirect political pressure recurs. A student in science and technology requires more costly and elaborate accommodation and equipment; and even if the number of arts students falls considerably, an increase in the number of students of science and technology would require capital expenditure on buildings and equipment. The University Grants Committee is firmly opposed to the continuance of the over-crowded and makeshift conditions which characterized the immediate post-war expansion, and quite rightly it postulates as an essential condition of any such expansion on the science and technology side that the necessary additions to accommodation and equipment shall be forthcoming. It emphasizes repeatedly that the position here is unsatisfactory and uncertain. Not only has the Government been unable or unwilling to undertake long-term commitments, but also the doubling in five years, instead of the ten years proposed by the Barlow Committee on Scientific Man-power, of the number of science students, as well as rising prices, have falsified completely the Committee's estimate in 1947 of the capital expenditure required for that purpose.

At this point the report of the University Grants Committee leaves the same outstanding impression as the Eighth Report of the Select Committee on Estimates, dealing with the schools, published a month or so ago. The building programme is quite inadequate for the educational aims Great Britain has set itself. In the universities as in the schools, aims and the allocation of resources must be brought into line. If the country wishes to increase its output of scientists and technologists, it must make the appropriate allocation of steel and other supplies, or the aim must be curtailed in keeping with whatever allocation the Government is prepared to make.

On what is said in this report, and confirmed by the Advisory Council on Scientific Policy and the Technical Personnel Committee of the Ministry of Labour and National Service, some such contraction in the number of arts students and an increase in the number of students of science and technology are both practicable and desirable in the national interest, and the University Grants Committee is prepared to support it if the necessary capital expenditure is forthcoming. Clearly, as the University Grants Committee puts the point, however, the necessary provision is unlikely to be made unless the Committee is supported to the fullest possible extent by the Advisory Council on Scientific Policy, the Parliamentary and Scientific Committee and professional bodies which have been urging the expansion of higher technological education as essential to the industrial well-being of Great Britain.

With the example of the Science Centre in mind, it is impossible to be over-confident that the Government will be convinced as to the necessity of the capital expenditure, and much more tangible support must be forthcoming from the world of science and technology as well as from industry than Sir Robert Robinson's patient and strenuous advocacy received. Indeed, it might be noted here that some capital expenditure on libraries may well be essential, and there can be no question that the establishment of the Science Centre would in itself have made quite an important indirect contribution towards easing the pressure on university libraries, both by catering for the specialist and by making it easier for university libraries themselves to specialize in ways such as the University Grants Committee suggests. Furthermore, the more widely the University Grants Committee is supported in pressing for such capital expenditure and the more clearly the purpose and necessity of such expenditure is generally understood, the less the risk that university expenditure may become subject to political pressure through the failure of politicians to face the realities of the situation.

It will be noted from this survey that the University Grants Committee does not advocate or anticipate any further expansion of the university population in the near future. It inclines to the view that there is little talent capable of benefiting by a university education which does not in fact reach the university; it is concerned rather with a redistribution inside the university which will avoid waste of public money by ensuring that, since more than two students out of every three receive some assistance from public or private funds, they are trained in ways likely to be to the public advantage. It recognizes, too, that considerations of economy require that the quality should be maintained, and no students should be admitted when incapacity to read for a degree might have been detected before they entered the university at all. Likewise, by implication, it indicates the importance of awards being financially adequate, and points to the possibility of vacation employment diminishing the value obtained from a grant as well as reducing the amount of grant needed.

In such passages as this, the University Grants Committee shows itself imaginatively alive to the problems which the universities and local authorities and other bodies making awards in Great Britain must face in the interest of the economic and social background from which university students are now drawn. These are sombre facts of which account has to be taken, and more could well have been heard from the Committee regarding the quality of students and the problems that arise from the presence in the universities of relatively large numbers of students who for various home reasons have difficulty in using the vacations for academic work. It cannot be assumed without more searching and critical inquiry that the main object of a university education, namely, to fit men for responsible posts and to train them to think, is being completely realized. The complexities of a technological age require that the affairs of State shall be handled with justice, skill and magnanimity no less than when Milton formulated his idea of a complete and generous education or Mill insisted that professional men should carry away with them from a university, not professional knowledge, but that which should direct the use of their professional knowledge and bring the light of general culture to illuminate the technicalities of a special pursuit.

The universities and the University Grants Committee, as this report and its predecessors over the past quarter of a century or so show, are manifestly seeking to avoid becoming detached, and to meet more effectively the changing needs of the community in which they exist. Nevertheless, it is plain that many students are working under handicaps in the way of cultural background as well as deficiencies in teaching or laboratory accommodation, halls of residence and libraries, which the economic situation has hindered the universities from remedying; such handicaps curb the imaginative consideration of the principles underlying a career that A. N. Whitehead described as the university's distinctive contribution in the preparation for an intellectual career. The significance of these difficulties is not so widely recognized outside the universities as it should be.

For such reasons a clear and authoritative statement or discussion of the purpose and character of university education is desirable. The University Grants Committee in this lucid survey indicates something of what is being done by the universities to meet these dangers and difficulties. It also suggests ways in which the universities could clarify ideas as to the functions of a university and what is expected of its alumni, as an essential preliminary to the determination of the nature and extent of the courses a university should offer. But public opinion also requires educating. It will be noted, for example, from this report, that in spite of the country's need for more technologists, the demand for technological education is slackening, as the Advisory Council on Scientific Policy noted earlier, and intending students show a marked preference for pure, over applied, science. The universities cannot provide places to which intending students are indifferent, or discourage undue specialization or honours courses, without the co-operation and understanding of both prospective student and prospective employer.

The report gives substantial reason for confidence that, in spite of a probable continuing trend towards greater accountability to Parliament on the financial side, academic autonomy will not be endangered thereby. It gives no grounds for believing that, through any lack of vision or vigour on the part of the universities or the University Grants Committee, the universities will get out of touch with the needs of the nation or become inefficient in the discharge of their responsibilities. The danger to university autonomy and to the maintenance of university standards is, however, real; but it arises from lack of public understanding, and to dispel the danger may require increasingly strenuous efforts of exposition and interpretation. This task of publicity, of educating public opinion to the real issues at stake, is perhaps one of the most important that immediately confronts the University Grants Committee. The account of its stewardship given to Parliament in the present report is no mean contribution to that end. More, however, will be required, and the University Grants Committee and the universities should be assured in that task of the support of all who value the principle of university autonomy.

ECOLOGY OF THE TROPICAL RAIN FOREST

The Tropical Rain Forest

An Ecological Study. By Prof. P. W. Richards. Pp. xviii+450+15 plates. (Cambridge: At the University Press, 1952.) 68s. net.

THERE has for a long time been the need for a modern account of tropical rain forests. Prof. P. W. Richards has adequately met this need if one takes into account the appendix to his title, "An Ecological Study". Not only does he include data from his own field researches in the rain forests of British Guiana, Sarawak, and Southern Nigeria, but he has also selected wisely from an extensive literature. Moreover, the book is well written, and both excess of ecological jargon and obscurities of style have been avoided without loss of scientific precision. Another pleasing feature is that it is frankly acknowledged that there are many problems connected with tropical rain forests that are not yet solved; but these problems are defined as clearly as possible and the solutions that have been proposed are fairly summarized and as fairly criticized. One may instance the theories of buttress formation (pp. 69–74) and Aubréville's mosaic theory of regeneration (pp. 49–53).

Prof. Richards very definitely proves the complexity of the ecological problems connected with rain forests. It may, however, be questioned whether the translated quotation from van Steenis (p. vi), referred to on p. 15, is either entirely logical or suggests the best practice. There are good arguments that the floras and types of vegetation of temperate regions have been derived from the much richer floras and communities of tropical climes. It does not follow that in floristic or ecological studies "one ought logically" to start with the richest, most difficult and most complicated. Much may be said in favour of starting with the poorest and (in general) simplest floras and vegetation—say, of the Arctic. This, of course, in no way diminishes the interest and importance of tropical plant life to any botanist who is not restricted in his outlook to the laboratory and arm-chair. Probably every ecologist and every taxonomist will support Prof. Richards in his plea for increased study of the tropical rain forest, for its preservation, and for a system of adequate (in situation, size and number) Nature reserves in the tropics fully protected under national or international administration. It is most convincingly shown in the postscript (pp. 404–7), under the heading "The Future of the Tropical Rain Forest", that humanity is suffering irreparable losses by the increasing destruction of tropical rain forests. It is not only the ecologist who will bemoan the losses, but also the taxonomist, the geneticist and, in the not too distant future, the exploiters, or their would-be successors, themselves.

It is impossible in a review of reasonable length adequately to survey the vast amount of information presented in "The Tropical Rain Forest". An introductory chapter defines the community by its general characters and outlines its history. The main body of the book is in sixteen chapters classified under six parts: structure and physiognomy; the environment; floristic composition of climax communities; primary successions; tropical rain forest under limiting conditions; and man and the tropical rain forest. Only a selection from the many interesting subjects dealt with in these 'parts' can be referred to here.

A great advance in method of study of rain forests was the use of the profile diagram, and the stratification, clearly shown in profile diagrams from forests in Asia, Africa and America, is discussed in detail (pp. 22–38). The trees constituting the bulk of the rain forest show many structural and developmental features, some of which are more or less clearly of selectional value under the given environmental conditions. This is also true for the shrubs, the climbers, the ground herbs, the stranglers and the epiphytes. The general controlling factors of the habitat are climatic: "high and very even temperature and heavy rainfall spread over the greater part of the year" (p. 135). As in other forest communities, the forest modifies climatic conditions within itself, with the resultant formation of microclimates. These involve all the climatic factors and are of very great importance for forest plants of all kinds, but especially for those below the highest or densest canopy layer. Many readers will find the chapter (pp. 191-204) on seasonal changes in the rain forest of particular interest. The environment is seasonally relatively uniform, and the text of the chapter is "Though the vegetation as a whole may show hardly any seasonal rhythm, the individual plants are seldom uniformly active". Leaf changes, growth and cambial activity, and flowering—that is, both vegetative and reproductive behaviour—vary with greater or less regularity from species to species. There is even periodic behaviour recorded for forest agarics by Corner in southern Malaya. The soils of the humid tropics are said to vary in structure, and in their physical and chemical properties, at least as much as those of any other climatic zone. The soils are, except the most immature, strongly leached. Laterization, the preferential leaching of silica from a soil, results in the formation of the lateritic red earths that may be the most widespread soil-type in the tropical rain-forest region. Sometimes very different soils are formed when the influence of the soil-forming material overrides that of the climate.

The composition of climax communities is illustrated in some detail from Prof. Richards's own studies in British Guiana and Sarawak. The recolonization of Krakatau is taken as an example of a primary xerosere (pp. 269–280), and hydroseres and coastal successions are considered in more general terms.

In dealing with the conditions limiting rain forest, deciduous forest and savanna have to be contrasted with it, both as regards their floristic and ecological structure and the environmental conditions favouring or limiting one or another community. The problems involved are of "bewildering complexity", but the conclusions reached (pp. 344–5) give a clear and fair summary of what is the best generalization with our present knowledge. Chapter 16, dealing with the tropical rain forest at its altitudinal and latitudinal limits, raises the many problems of zonation and provides numerous data to be considered in reaching their solution.

Man has destroyed large areas of virgin or primitive rain forest. Where cultivation is not continuous, secondary and deflected successions occur. Apparently, little close study and systematic observation have yet been carried out on these communities, and continuous observations over a long period of years are needed. However, the general features of secondary rain forest and its composition and origin are outlined, and incomplete descriptions of secondary successions are given for Nigeria, the Congo, the Malayan region and tropical America.

"The Tropical Rain Forest" will be a stimulus to further research. Prof. Richards would be among the first, and best qualified, to say that there is need for as many investigators as possible. It is important to remember that his book is "an ecological study" or, better, a plant ecological study. Apart from vegetational problems of the rain forest known but not solved or even still unformulated, there are many others to which this book must, in some degree, form a background. The floristic composition and the history of the rain forests are considered in connexion with the ecology, not as subjects *sui generis*. The historical relationships of the American, African, Asiatic and Australasian divisions of the 'panformation' of tropical rain forests raise unnumbered questions. The animal life of rain forests is a vast subject linked to the plant life. The tropical rain forest is not the only plant formation of the tropics. In particular, one would welcome a study of tropical savannas as full and as up to date as that now provided in this book.

For no very clear reason the book is dedicated to "The memory of Carl Schroeter". Carl Schroeter was a pioneer in ecological studies of Central European vegetation in particular and mainly, and I cannot recall that he did noteworthy work in connexion with the tropical rain forest. There is no reference to a single work by Schroeter in the sixteen pages of references provided by Prof. Richards, though he is once quoted in the text (p. 10) at second-hand. One might have thought that a dedication to, say, A. F. W. Schimper would have been more appropriate.

In conclusion, this is a most important book to ecologists, plant geographers and taxonomists. It can surely be read with enjoyment and profit by all botanists and by many who would not claim a special knowledge of plant life. It is not merely a book of reference or a text-book or a tome to be interpreted only by specialists. It will be often referred to, it will be read by university students, and it will be frequently consulted by specialists. In addition, it is a book that can either be read straight through as an occupation with mental gain for many evenings or one that can be delved into, for most of the chapters, and even sections of chapters, are so far self-contained as to be fully understandable and, in a sense, complete in themselves. W. B. TURRILL

TREATISE OF ZOOLOGY

Traité de zoologie

Anatomie, systématique, biologie. Publié sous la direction de Prof. Pierre-P. Grassé. Tome 1, Fascicule 1 : Phylogénie ; protozoaires, généralités ; flagellés. Pp. xiii+1071. (Paris : Masson et Cie., 1952.) 9,600 francs.

THIS is another volume of the now well-known "Traité de Zoologie", issued under the editorship of Prof. Pierre-P. Grassé, of the Sorbonne. While the seventh to appear, it is in fact the first fascicle of the first volume of the series and is in every way worthy of its predecessors. Its 1,071 pages are provided with 829 illustrations (there is no Fig. 285), 694 in line-drawings, 116 in half-tone from wash drawings, 18 in half-tone of photographs and 1 in line and colour. The last is so effective that it is somewhat surprising that this technique has not been employed more often. This figure has a disadvantage in that the reference letters in the legend are not alphabetically arranged, *Ect.* in the figure is given as *Et.* in the legend and two reference letters in the figure are not explained. The figures, as in previous volumes, reach a high standard and some of the line-drawings are exceptionally good. As before, a number of authorities have contributed to the contents. Since it is the first volume and deals with certain groups of the Protozoa, Prof. Grassé contributes a good deal. The other contributors, Prof. L. Cuénot (Nancy), Prof. E. Chatton (Sorbonne), who unfortunately died before all his sections were completed, M. G. Deflandre (National Scientific Research Centre, Paris), Prof. A. Hollande (Algiers) and Prof. J. Pavillard (Montpellier), are sufficiently distinguished in their own fields to assure the authority of their individual contributions.

The volume commences with a general discussion on the evolution of the animal kingdom with the view of devising a scheme of classification ; this, as might be expected from the editor, is a thoughtful and useful essay. Fig. 4 on p. 23 presents a schematic classification of the whole animal kingdom in the form of a phylogenetic tree. On the whole, this is acceptable but is open to criticism on a major and at least one minor point. The major point concerns the position of the Platyhelminthes and Nematoda. The tree divides into two main trunks, one containing the Echinodermata, Protochordata and Chordata, and the other all the remaining animal groups. The division takes place as from the Cœlenterata, and the Platyhelminthes and Nematoda are regarded as cœlomates (pp. 18, 25) ; the more modern view is that these two phyla are not to be regarded as cœlomates that have had their cœlom obliterated or afterwards modified but rather as phyla that have not yet reached the stage of evolution in which a cœlom has made its appearance. They are acœlomate, triploblastic Metazoa. The minor point is the interposition of the Carnivora between Cheiroptera and Primates.

The editor next discusses the position and classification of the Protozoa and directs attention to the difficulties they present. He has gone back to the old name Protista, given by Haeckel in 1866, and recognizes a Phylum Protista which includes both the branches (*embranchements*), Protozoa and Protophyta, which cannot be clearly separated from one another. He employs the term phylum in a higher ordinal sense than is general in Britain, for he recognizes only two phyla of animals—the Protozoa and the Metazoa—and so his term *embranchement* corresponds more closely with our phylum. Transposing the terms in this way, he divides the Protozoa into five sub-phyla as follows: the Rhizoflagellata containing the more general Rhizopoda and Flagellata, again combining them because of the overlap; the Actinopoda (Acantharia, Radiolaria and Heliozoa), the 'pseudopodia' of which are of a fundamentally different type from those of the rhizopods; the Sporozoa; the Cnidosporidia; and the Ciliata. While perhaps this classification may not meet with general acceptance since it differs so noticeably from what may be called the orthodox, it is logical and deserving of careful consideration in view of the arguments put forward in support of it. What may surprise most general zoologists is the transference of the opalinids from the ciliates to the flagellates.

The present volume deals only with the general introductory matters and the sub-phylum Flagellata. The introductory accounts of the structure, physiology, nuclear behaviour, life-cycle and biology of the various categories form a valuable part of the work. Under the systematics of each class there is, wherever possible, a section dealing with its fossil members, a reminder of the present interest in microfossils. It is regrettable that the exigencies of the times are reflected in the price, for this highly commendable book should be readily accessible to every zoologist.

C. H. O'Donoghue

HYDROGRAPHY IN FISHERIES RESEARCH

Hydrography in relation to Fisheries

Being the Buckland Lectures for 1938. By Dr. John B. Tait. Pp. xii+106. (London: Edward Arnold and Co., 1952.) 7*s*. 6*d*. net.

The Buckland Lectures are given each year to varied audiences by a scientific worker engaged in fisheries research. Before the 1938 series, the Lectures had been given by biologists or zoologists; the series just published differs in that Dr. J. B. Tait makes his contribution as a physicist interested in the sea itself rather than in its animals. An introduction explains the subject of hydrography (or physical oceanography) and, with examples, justifies the existence of a hydrographer in a fisheries laboratory.

In Chapter 1 Dr. Tait discusses the effects of physical conditions in the sea upon fishes. He deals at length with the part played by temperature in determining the geographical distribution of the various species and collates the results of many workers in this field during the past fifty years. Evidence that spawning is stopped by abnormally high or low temperatures is given, and this is followed by a table listing the ranges of temperature, salinity and depth in which the various species of fish are found. Once the fish have spawned, the rate of development of eggs is largely influenced by the water temperature; for example, herring eggs hatch in under a week at 14° C., but would take about seven weeks at 0–1° C. Growth of the larvæ similarly is more rapid at the higher temperatures; off the east coast of Scotland spring-born herring grow in length and weight more quickly than those born in August and September. Before leaving the influence of temperature on adult fishes, Dr. Tait mentions the exceptionally cold winter of 1928–29 during which large numbers of fish were killed by the extreme conditions. These facts were corroborated during the early months of 1947 in similar conditions. The effects of salinity, light intensity, viscosity of the sea water, and osmosis are briefly discussed.

One of the most interesting aspects of hydrography is the study of currents in the sea. Dr. Tait mentions several approaches and then gives a fairly comprehensive account of his own work with drift-bottles in the northern North Sea and adjacent regions. The manner in which the information accruing from the recapture of bottles is used by the scientific worker in constructing a picture of the current systems over wide areas is described. The importance of a knowledge of these systems is stressed and illustrated with many examples, one of which is the controversial question of fish migrations. The most widely accepted theory suggests that migrating fish swim against the current, and is apparently supported by the movement of eels in the Atlantic Ocean, of cod near Iceland, and of plaice in the Shetland Islands area, to quote the text. Dr. Tait adds that "as the knowledge of currents grows in detail, so will this theory receive the greater confirmation".

In Chapter 2 the reader is taken into the chemical department of the hydrographer's laboratory. He is introduced to the difficulties in analysing sea water and to the importance of such characteristics as hydrogen-ion concentration. In the sea where the concentration of the nutrient salts approaches, and often falls below, the limit required by marine organisms, it is obviously desirable to measure these concentrations; chemical oceanographers have worked out methods to estimate the number of parts of these elements per thousand-million parts of sea water, and the effects of their variation on fisheries can now be studied.

In his last chapter, Dr. Tait relates fluctuations in the abundance of fishes to hydrographical conditions in their environment. A diagram showing sea temperature and monthly catches of haddock would appear to indicate a complete explanation of the varying catch; but, as stated, the solution is not so simple. Dr. Tait presents the outline of his argument for the relation between fishery fluctuations and the incursions of Atlantic oceanic water into the North Sea. Although obviously aware of the scarcity of suitable hydrographical data, he finds support in a similar environment in the English Channel. It is interesting to read a note appearing in *World Fishing* of January 1953: "Reports from the Baltic indicate that the salinity there has increased considerably in recent years. As a consequence, the inflow of cod has been better and, although previously cod did not appear in Finnish waters, Finnish fishermen are now obtaining reasonable catches".

In closing, Dr. Tait would welcome more systematic and intensive measurement of hydrographical factors; but it will be apparent to all readers of his book that important steps have been made in spite of the difficulties in observing at sea.

David Vaux

THE UNIVERSITIES OF GREAT BRITAIN: POSITION AND PROSPECTS

To assist the Treasury in considering the provision which Parliament should be asked to make for the next quinquennium, the University Grants Committee early last year issued an interim report on university development in Great Britain during the four years 1947–51. That interim report largely dispelled misgivings currently entertained as to the effect of economy measures on university development. The complete factual record for the whole quinquennium of the use to which the universities have put the greatly increased financial resources which have been at their disposal now available* is no less reassuring. Following the lines of earlier reports, the present one reviews the whole of the quinquennium 1947–52 and discusses some of the principal problems of general policy with which the universities are currently confronted. In general, it confirms the impression given by the interim report, material from which is freely repeated, that the main task of the universities during the coming quinquennium will be that of consolidating the ground won by the advances of the past five years.

The broad features of the situation have been made generally familiar not only by the interim report but also by current and continuing discussion on the expansion of technological education, the training of scientists and administrators, the control of public expenditure and the relations between industry and the universities in Britain. The work of the University Grants Committee continues to grow, and it is now concerned with eighteen universities and four separate university colleges, as compared with sixteen and five, respectively, at the beginning of the quinquennium, and two colleges of technology, although the charter as a university obtained by the University College of Southampton did not take effect within the quinquennium under review.

Looking first at student numbers, during 1951–52, the last year of the quinquennium, the number of full-time students enrolled in the universities and colleges was 83,458, compared with 78,507 in 1947–48, 66 per cent greater than in 1938–39, the last year before the Second World War, and only two thousand less than the peak figure (85,421) of 1949–50. Apart from the temporary increase due to the influx of ex-service men and women, assisted by the further education and training scheme, these numbers reflect a permanent increase which indicates the extent to which the universities have already responded to the demands for more graduates formulated in the Barlow and other reports. There were during 1951–52 twice as many students of science and technology as there were during 1938–39. Arts students increased by 60 per cent, students in agriculture by 132 per cent, medical students by 17 per cent, dental students by 94 per cent, and veterinary students were nearly four times as numerous. The expansion in science and technology was thus completed in five years instead of the ten contemplated by the Barlow Committee; but the objective of the Teviot Committee has not been reached, chiefly because numbers of suitable students have not come forward. The consequent changes in the total student body are shown in Table 1.

The University Grants Committee pays tribute to the resourcefulness and adaptability which the universities displayed in coping with these increased numbers, and notes that inconveniences of overcrowding were willingly endured in the hope, so far unfulfilled, that a rapid increase in the rate of university building would soon become possible. This still appears to be unlikely, and the experience of these years obviously determines the Committee's attitude to the further expansion of the student population. It is concerned, above all, to maintain standards, and the Chancellor of the Exchequer is reminded very firmly that any increase in the number of students of science and technology involves capital expenditure on buildings and equipment, even if the number of arts students fell at the same time.

The increase in student numbers during the quinquennium was not spread evenly over the universities and colleges. For England as a whole, the figures for 1951–52 were 70 per cent above those for 1938–39; but at Oxford and Cambridge the increases were only 41 per cent and 34 per cent, respectively, and at London no more than 39 per cent, compared with an average of 127 per cent for the remaining English universities and university colleges. In Wales the increase was 75 per cent, and in Scotland 49 per cent. Students with homes in the United Kingdom increased in number by 71 per cent, the number from overseas increasing by 33 per cent (from 5,213 to 6,960), or just over 8 per cent of the student population, compared with 10 per cent in 1938–39, more than half still coming from countries within the British Commonwealth and 57 per cent going to Oxford, Cambridge or London, compared with about 66 per cent before the War.

The University Grants Committee thinks that there are good reasons for assuming that the rapid rate of increase in total student numbers which marked the immediate post-war period is likely to be followed by a slight fall during the next few years. Practically every university institution has been full to, or beyond, its reasonable physical capacity, and even if university institutions were themselves willing to accept any substantial increase in student numbers without the addition of new buildings on a scale unlikely to be possible immediately, the University Grants Committee is clearly and rightly opposed. "The quality of education cannot but be affected by the surroundings in which it is given and it would not be in the interest of university education that the discomforts and handicaps of overcrowded and makeshift accommodation should be endured for an indefinite period." It appears to lean rather to the view that the right policy at the present juncture may be to relieve congestion by contracting slightly the intake of students, particularly if it is true that

Table 1. Full-time Students in Faculties

	1938–39		1951–52	
	Number	Per cent	Number	Per cent
Arts	22,512	44·8	35,936	43·1
Science	7,767	15·5	17,053	20·4
Technology	5,288	10·5	10,215	12·2
Medicine	11,883	23·6	13,910	16·7
Dentistry	1,488	3·0	2,889	3·5

Veterinary science	265	0·5	1,037	1·2

---

* University Grants Committee. University Development, Report on the Years 1947–1952. (Cmd. 8875.) Pp. 93+8 plates. (London: H.M.S.O., 1953.) 3s. 6d. net.

few school-leavers who desire, and are capable of profiting by, a university education, would fail to gain admission, provided they are prepared to go to an institution other than that of their first preference. That policy is supported by other considerations noted in the report, and implies that any further increase in the student population of the universities should wait on an increase in the output of suitable pupils from the secondary schools.

The University Grants Committee does not, however, rule out the desirability of changes in distribution between faculties. It is doubtful whether the future demand for arts students will be sufficient to absorb the entire output of the universities at its present rate, and there are certain fields of vocational training, notably science teachers, dentists and some categories of scientists and technologists, from which a substantially higher output is urgently desirable in the national interest. It infers accordingly that, during the next quinquennium, the proportion of students engaged in scientific and technological studies will tend to grow at the expense of the proportion of arts students. Reference has already been made to the financial implications of such a transfer; but so far as recurrent expenditure is concerned, the Committee is reasonably confident that such adjustments of the balance of the faculties as the needs of the next few years may dictate will not be unduly hampered by lack of income. Furthermore, the Committee, pointing to the difficulty of assessing demand for specialized fields like the branches of biology, where in any one year the demand may be very small, suggests that employers requiring men with this kind of training should consider selecting them before they commence post-graduate training, paying the selected individuals' salary and fees for that training. Moreover, figures indicating the pressure to enter the various faculties afford little support for the view that men choose the faculty in which they would propose to read mainly by reference to the salaries to be expected on completion of training.

Reviewing the numbers of students in relation to population, the report notes that, assuming the survival of 90 per cent of live births to age eighteen, the proportion of any age-group which reaches the university is now about 1 in 31 compared with about 1 in 60 before the War. As the annual number of live births in Great Britain began to rise steeply in the latter part of the War, reaching a peak average of 932,000 in 1946–48, a marked increase in student numbers will be required from about 1960 onwards if the proportion of each age-group which reaches the university is to be maintained. Broadly, it appears to be true to say that the differences between England, Wales and Scotland in the proportion of any age-group which reaches the university have greatly diminished. While the Committee thinks that to aim at raising the university student population to the American scale by lowering entrance standards to that of the American college would be unwise and would alter the whole character of our universities, it would welcome an increase in the student population subject to three conditions: first, there should be no increase in any faculty that would lead to difficulties in finding satisfactory employment for its graduates; secondly, the necessary additions to accommodation and equipment should be forthcoming; and third, it should involve no decline in the standard reached by students when they obtain their first degree.

This last condition probably means that if the other two were satisfied and the time were ripe, until the rise in the birth-rate takes effect, the increase could only come through the retention in the grammar schools of a greater proportion of the more intelligent pupils who now leave prematurely. The report also directs attention to the change in the economic and social background of the students which has occurred during the past two or three decades. Whereas the percentage of all full-time students receiving assistance in the way of scholarships, exhibitions or other awards from public or private funds in 1938–39 was 41·1, in 1951–52 it was 72·4, and at one stage the proportion at Oxford and Cambridge rose as high as 82·2 and 79·8 per cent, respectively. The position is further displayed in Table 2, and it should be further noted that the number of unassisted students has declined absolutely, as well as relatively, from 29,456 in 1938–39 to 23,006 in 1951–52, almost entirely in Oxford, Cambridge and London.

Table 2. ASSISTED STUDENTS AS A PERCENTAGE OF ALL FULL-TIME STUDENTS

	1938–39	1951–52
England		
Cambridge	39·0	67·8
London	26·0	67·7
Oxford	55·2	71·7
Other universities and university colleges	44·4	79·5
Total		
England	38·5	73·8
Wales	61·4	88·3
Scotland	45·1	61·6

One consequence has been that a much higher proportion of students than formerly are young men and women who have few cultural interests and attainments beyond those which they have acquired at school. Their presence in the universities has forced upon the universities various problems of teaching and the organization of student life which were not previously generally recognized, and the solution of which may be assisted by the fact that the academic staff are increasingly drawn from the same strata of society as the students.

As regards quality of students, it seems that in relation to the total number of students, the proportion of outstandingly good and outstandingly weak students is lower, and that of good second-class students higher, than it used to be. There is probably also a continuing tendency for a higher proportion of the abler school-leavers to seek admission to the scientific faculties; but the demand for technological courses is less keen than that for pure science. Despite the reassuring impressions of student quality derived from the Committee's visits to universities, its general conclusion is that no further substantial increase in student numbers could be expected in the immediate future without reducing university standards. It is not disturbed by present casualty-rates, but would deplore alike any tendency to admit to a first year of study students whose incapacity to read for a degree could have been detected before they entered the university at all, or to regard the award of a degree as automatic once admission to a university is granted. Nevertheless, the University Grants Committee thinks that in general the problem of selection is receiving the attention it deserves. It considers that the response to steps taken to stimulate wider interests among students has been most encouraging; but it gives a caution about vacation employment and suggests that the question of vacation study may require further attention.

Although a few new university halls of residence have been erected during the quinquennium, the addition of 7,500 places since 1938–39 has done little more than maintain the pre-war proportion of students in residence. This is one of the outstanding disappointments of the past quinquennium; but in accepting the fact that there is little prospect of any immediate and considerable expansion of the residential system, the Committee does not wish to discourage universities from thinking ahead to a period when building on a larger scale can be resumed. It points out, however, that the extent to which students should reside in halls can be over-stated, and that residence in hall is not necessarily the best arrangement for every student at every stage of his career. Further, it is desirable meanwhile to do all that is possible to develop other agencies for promoting communal life and to keep students in the university atmosphere at times when they are not required to be in attendance at lectures. As regards student health, it is suggested that provision for this requires reconsideration in the light of the general principle that university schemes should aim at satisfying the special and distinctive needs of student life rather than providing a duplication of the National Health Service.

While the increase in students came early in the quinquennium, the increase in academic staff, from 3,994 during 1938–39 to 5,561 during 1946–47 and 8,952 during 1951–52, came later. It was not until the later years of the quinquennium that the flow of suitably qualified candidates enabled the universities to recruit new staff in sufficient numbers to meet the needs of the enlarged student population; but the staff : student ratio (excluding Oxford and Cambridge, for which comparable figures are not available) has risen from 1 : 10 in 1938–39 to 1 : 8 in 1951–52. Nearly all the universities and colleges in Britain have been able to develop to some extent a tutorial system, particularly for the benefit of their senior students. The Committee believes that the doubling of the academic staffs has not involved any deterioration in quality; but it points out that the full financial effect of this expansion has not yet been felt, and the low average age of the academic staffs in most universities has repercussions which require attention in recruitment policy in the creation of new posts, such as readerships, and in considering the age of retirement, if serious promotion blocks are to be avoided. The report gives a clear account of the present salary position and of the unavoidable differentiation between medical and non-medical staff. It stresses the importance of an improvement in the staff : student ratio; but while fully supporting the view that the university teacher should be able to devote an adequate proportion of his time to research or other original work, it deprecates any idea that the potential value of a young member of a university staff can always be judged by his or her output of research or scholarship before the end of three years service as an assistant lecturer.

More is said about research in the following section of the report. The University Grants Committee does not believe that there is any immediate danger in Great Britain of the universities devoting an undue share of their research activities to the fulfilment of government contracts. In the years ending July 31, 1950, and 1951, the universities received from government departments and the research councils, for specialized research, including some capital, £1·6 million and £1·7 million, respectively, compared with a total revenue expenditure of the universities in these years of £22 million and £24 million, respectively. On the other hand, it is pointed out in regard to nuclear research that, while this is a continuation of a field of investigation which was attracting many notable physicists before the War, and it is desirable both that some university research workers should have access to the large machines provided at such universities as Cambridge, Oxford, Birmingham, Liverpool and Glasgow, and that a proportion of those undertaking physics research in other universities should devote themselves to nuclear investigation, it would be unfortunate if preoccupation with this particular branch of physics were to distort the general balance of research. The Committee states that it does not propose to continue, in the quinquennium 1952–57, the practice of recommending non-recurrent grants for the purchase of new equipment for existing accommodation, though such grants will continue to be available, as may be necessary, for furnishing and equipping new accommodation. Of non-recurrent grants for this purpose during the quinquennium, totalling £7 million, some was for bringing the equipment of existing laboratories up to an appropriate level, and the Committee believes that the average scientific worker in the university is now far better equipped for prosecuting his research activities than at the beginning of the quinquennium.

The Committee refers to the importance of avoiding overloading of the curriculum for a first degree and urges that in designing such courses of study the consideration that universities have to educate men and women capable of holding positions of responsibility in every walk of civil life should always receive its due weight. Students of all levels of ability will derive benefit from their courses only if they learn to think. Reference is also made to the inquiry into ways of learning by students of university age which the Committee is sponsoring by an *ad hoc* grant; and while welcoming the increased allocation to libraries proposed in the quinquennial estimates of many universities, the Committee also stresses the value of the possession of even a small private library. Expenditure by university libraries on the purchase of books and periodicals has risen from £87,802 during 1938–39 to £321,269 during 1951–52; but great difficulty is constantly experienced in meeting the legitimate demands of students and staff. Moreover, pressure on space has developed from increased buildings as well as from the increase in readers to be served, and the report holds out little prospect of any early alleviation of the position by new building. The suggestion is made that university libraries may need to be highly selective and that the possibilities of 'weeding' should be fully exploited. The Committee has also decided to terminate the ear-marking of grants, and has informed the universities that while it does not propose that any part of the recurrent grants for the new quinquennium should be formally ear-marked to support developments in the special fields which were initiated during the past quinquennium, it has taken this step on the assumption that in allocating their income the universities will treat the developments of the 1947–52 quinquennium in these fields no less favourably than other departments. The Committee has asked any university which proposes to curtail any development initiated with the aid of an ear-marked grant to consult the

Table 3

	1947–48	1948–49	1949–50	1950–51	1951–52
	£	£	£	£	£
Total recurrent (including ear-marked) grants	8,850,455	10,317,775	13,635,470	15,222,408	1,660,113
Medical education	1,840,350	2,149,800	2,565,500	2,885,000	3,198,500
Dental education	157,150	206,000	237,000	268,000	300,000
Agricultural education	150,000	262,000	299,500	327,850	361,600
Veterinary science	12,500	28,800	116,800	276,750	412,500
Social studies	102,000	160,000	240,000	320,000	400,000
Oriental and African studies	55,000	125,000	148,500	178,000	200,000
Slavonic and East European studies	15,225	30,975	36,875	42,825	49,800
Institutes of education	20,230	79,570	131,904	155,499	171,463
Ear-marked grants as a percentage of total grants	26·6	29·5	27·7	29·2	30·7

Committee before a final decision is taken. The totals for each year of the quinquennium of the recurrent grants allocated and of the ear-marked grants for each special field are given in Table 3.

Non-recurrent grants approved in the period August 1, 1947–July 31, 1952, amounted to rather less than £35 million, as compared with the estimate in January 1947 of capital needs for the quinquennium of £40 million for new building and £10 million for sites and equipment, or about half the capital expenditure regarded as required, at 1947 prices, to give effect to the Barlow report over ten years (instead of the actual five in which the expansion was realized). Of this sum, £23 million was in respect of building, more than £4 million for the purchase of sites and properties and £7 million for provision of furnishings and equipment. Actual payments during the quinquennium totalled £26 million, and at its close more than £11 million of approved grant awaited payment. Some indication of the way in which the universities have met the situation arising out of the reductions in the investment programme and the rationing of steel by adapting their building programme is given by illustrations included with the report.

The outstanding feature of university finance during the quinquennium has been the increase in the proportion borne by recurrent Treasury grants to the total income of the universities, from 31·4 per cent in 1938–39 to 64·5 per cent in 1951–52. The original and ultimate Treasury provision for each year in the quinquennium is shown in Table 4.

Income derived from local authorities in England and Wales increased by 50·9 per cent, from £626,947 during 1946–47 to £945,972 during 1951–52, that from tuition and examination fees increasing from £3,022,634 to £3,807,440, while in the same period "Other income" increased by 113 per cent, from £910,032 during 1946–47 to £1,936,596 during 1951–52. Annual expenditure rose from £12,694,227 to £26,132,122, almost half of this being due to the increased cost of salaries and superannuation of teaching staff, which rose from £5,956,248 during 1946–47 to £12,542,994 during 1951–52, the average salary of a full-time university teacher increasing by about 32 per cent. Other expenditure rose from £6,737,979 to £13,589,128 or 102 per cent, that under the heading "Departmental and Laboratory Maintenance", which was more severely affected by rising prices than that under any other head, accounting for £3,174,295 of this increase. Maintenance of premises increased by 98·5 per cent and administration by 94 per cent, due partly to increased staff required by the higher level of university activity, partly to salary and wage increases and partly to increases in prices, notably in paper and printing.

Table 4

Ultimate total provision	9·16	10·61	13·65	15·33	16·71

Some remarks are made on particular fields of study. Regret is expressed, for example, that little appears to have been done to carry out the recommendations of the Goodenough Committee for lightening the medical curriculum, and also that in some institutions the course for a degree in dentistry appears to be longer than is necessary. The arrangement by which, with the co-operation of the general practitioners in the area, students receive during part of their clinical period instruction directly related to the conduct of general practice is commended for imitation.

A statement of the additional science subjects for the development of which block grants have been given is appended to the report, and the Committee is satisfied that the only major subject in which additional facilities appear to be required is biochemistry. In regard to technology, it observes that in the universities as a whole the demand for entry into technological faculties from students of acceptable standard is not greater than the universities can meet, but entry into science faculties has continued in most places to be more competitive. While agreeing that the number of those taking technology in the universities should be increased, the Committee does not advocate a uniform increase in all faculties of applied science or technology, or that technologists should constitute a similar proportion of each university. It suggests rather seeking to increase the number of students of technology in those universities where it is already high, on the ground that it is most economic to make provision for subjects in which large and expensive apparatus is required in a few centres. It is convinced, however, that scarcely any centre can cover the full range of technological subjects, since the activities of an institution must be in part related to those of the area which it serves. On management, it suggests that any course which teaches a man to think, broadens his mind and develops his personality, fits him for a position of responsibility ; but otherwise education for management is best concentrated in postgraduate courses.

THE BRITISH INSTRUMENT INDUSTRIES' EXHIBITION

THE second exhibition of the British Instrument Industries was held during June 30–July 11 in the National Hall, Olympia, London, two years after the first. It is the intention of the sponsors—five trade associations concerned wholly or partly with instrument manufacture—and organizers to make the exhibition a biennial event.

The confidence in the value of the exhibition shown by these plans seems to be justified: the second exhibition had more exhibitors than the first; the exhibitors, numbering 168, represented adequately the British instrument industries and included most of the large firms and many of the smaller ones; and the products displayed (of 414 kinds, according to a count of the subject headings of the classified index in the catalogue) were representative of the scientific and industrial instruments made in Great Britain. The hall, which was well set out, appeared to be comfortably filled and the exhibitors busy.

The instruments on show, too numerous to be described individually, revealed one general and well-recognized trend and several local and less obvious ones. The general one is, of course, the increasing extent to which almost every type of modern instrument incorporates, and is dependent upon, electrical or electronic components or accessories, which are therefore expected to be almost as reliable and trouble-free as the cases and stands themselves.

Apart from this general trend, some small but probably significant changes are discernible. Thus there appears to be an increasing number of instruments made for non-destructive testing, and particularly for thickness gauging, with special emphasis on the measurement of the thickness of electro-deposits and coats of paint. The application of radioactivity is becoming more common and new uses are being found: one exhibit was an ionization anemometer, where the rate at which air ionized by a radioactive source is blown away provides a measure of wind velocity. Strain gauges are becoming ubiquitous research tools, and are taking on new forms, incorporated, for example, in compact, hermetically sealed load cells.

Some of the exhibits provided encouraging evidence that there is not always as long a delay in developing commercial models of instruments from the products of the research laboratories as is often supposed. The flying-spot microscope, the possibilities of which were pointed out by Roberts and Young as recently as 1951 (*Nature*, 167, 231; 1951), was on show (not for the first time) and was no longer regarded by visitors as a novelty. Recent work on the production of transparent conducting coatings on glass for de-icing instrument windows or preventing static charges from building up on them has already borne fruit in commercially available indium, cadmium oxide, and gold coatings on glass squares with light transmissions up to 90 per cent (indium) and resistances from 5,000 (indium) down to 15 (gold) ohms. This augurs well for the prospects of early development of commercial models of some of the useful prototype instruments —a simple radiometer, a capacitance-resistance hygrometer, and a voltage stabilizer, to mention three—shown on the stand of the Department of Scientific and Industrial Research by some of its establishments and the research associations.

The exhibition has brought to mind three matters which might well be given further consideration before the next one is held. First, is the word 'Celsius' to be used instead of 'Centigrade' in accordance with the International Temperature Scale adopted internationally in 1948? Many exhibitors marked their instruments '°C.'; but of those who used a complete word, only one was noticed to have employed 'Celsius'. Second, are the results of the recent work by the Naval Motion Study Unit and others on the design of dials and indicators generally applicable? Third, can substantial effort be devoted to finding means of reducing reflexion from instrument windows? With the prevalence of rows of panel-mounted instruments observed by one man who sees each instrument from a different angle and cannot, therefore, avoid reflexions from all of them by moving his head, this trouble has become serious.

OBITUARY

Dr. Tom Goodey, O.B.E., F.R.S.

DR. TOM GOODEY, who died suddenly on the evening of July 7 on his way home from a Friends' meeting, was born at Wellingborough on July 28, 1885. He was educated at the County School, Northampton, and at the University of Birmingham, where he took the degrees of B.Sc. (with honours in zoology and botany) in 1908, M.Sc. in 1909 and D.Sc. in 1915. In 1910 he was elected to the Mackinnon Studentship of the Royal Society. During the year 1912–13 he was protozoologist at Rothamsted Experimental Station and returned there in 1920 after serving during 1913–19 on the staff of the laboratory of agricultural zoology attached to the Department of Zoology at the University of Birmingham. In 1921 he was transferred by the Ministry of Agriculture to the agricultural section which the Ministry subsidized in the Department of Helminthology at the London School of Tropical Medicine. When this Institution became incorporated in the new London School of Hygiene and Tropical Medicine, the Development Commission provided the School with a field station, for the work on agricultural helminthology, at Winches Farm, St. Albans, which later became generally known under the title of Institute of Agricultural Parasitology. There Goodey worked from 1926 until 1947 and ultimately became a principal scientific officer. On the retirement of its director, those members of the staff who were engaged on research into plant-parasitic nematodes were transferred by the Ministry of Agriculture to Rothamsted, and Goodey became head of the new Nematology Department there. Although he retired from this position last year, he continued to take an active share in the work of the Department up to the day of his death.

Goodey's earlier researches were mainly concerned with the activities of Protozoa in the soil; but the investigations by which he acquired an international reputation were those on the nematodes parasitic in and on plants, and the related forms present in soil and fresh water. In 1933 he published "Plant-Parasitic Nematodes and the Diseases they Cause". This was followed in 1951 by "Soil and Freshwater Nematodes"—the first comprehensive monograph on this subject in the English language.

All his scientific writings were characterized by a clarity and felicity of expression and illustrated by a fine series of line drawings, to the preparation of which he devoted much care and skill. His work was to him a source of continual delight. He lived a life of imperturbable serenity, deriving additional pleasure from gardening and music. He was the fortunate possessor of a fine tenor voice, which he gladly used on innumerable occasions to assist local charities and to contribute to the social life of the community in which he lived.

In 1947 Goodey's outstanding contributions to science were recognized by his election to the fellowship of the Royal Society, and those to agriculture by his appointment in 1950 to be an Officer of the British Empire.

R. T. LEIPER

NEWS and VIEWS

The Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme

THE Royal Society and the Nuffield Foundation are to initiate jointly a Commonwealth Bursaries scheme. The Nuffield Foundation is supporting this bursary scheme as a complement to its established programme of Commonwealth fellowships and other awards. The objective of the scheme is to provide facilities for increasing the efficiency of investigators of proved worth by enabling them to pursue research, learn techniques or follow other forms of study where either or both the physical and personal environment overseas in the Commonwealth is peculiarly favourable. The main difference from the ordinary research fellowship is one not merely of duration but also of emphasis, as the bursaries will aim not so much at obtaining the answer to a particular question as at improving the powers of the recipient to extend the bounds of knowledge. The scheme will be operated for an experimental period of five years during which time the Nuffield Foundation will provide £5,000 a year, and this will be devoted to bursaries to United Kingdom scientists who wish to go to oversea parts of the Commonwealth and to scientists of one oversea part of the Commonwealth to go to another. Initially the Royal Society will also make a contribution of £2,500 which will be available for movement in any direction within the Commonwealth, including to the United Kingdom. It is, however, hoped that funds may be obtained from other sources, particularly from overseas, to make possible the full development of the scheme especially by increasing the proportion of bursaries available for scientists of oversea countries of the Commonwealth who desire facilities in the United Kingdom. Each bursary will provide for the cost of travel and maintenance normally for periods of 2–12 months. It will not aim at the provision of any salary as such but will supply maintenance. The applicant must be sponsored by a recognized research authority and must produce evidence that he or she has prior permission to work in the laboratory or other scientific institution chosen. It is expected that in the operation of the scheme Fellows of the Royal Society throughout the Commonwealth will assist in sponsoring and assessing applicants for bursaries.

A joint Royal Society and Nuffield Foundation Commonwealth Bursaries Committee has been set up to administer the scheme on behalf of the sponsors. Its membership is as follows: *Chairman*, Sir Edward Salisbury; *Nominated by Trustees of the Nuffield Foundation*, Mr. Leslie Farrer-Brown, Sir John Stopford and Prof. A. R. Todd; *Nominated by Council of the Royal Society*, Prof. G. R. Cameron, Prof. H. S. W. Massey and Sir Eric Rideal, with Dr. D. C. Martin, assistant secretary, Royal Society, as secretary to the joint Committee. It is proposed initially to consider applications at six-monthly intervals beginning early in 1954. Application forms containing further details will be obtainable from the Assistant Secretary, the Royal Society, Burlington House, Piccadilly, London, W.1, and must be submitted not later than March 15 and September 15 each year.

Royal Society Research Appointments

THE Council of the Royal Society has made the following research appointments: Mr. P. J. Black (University of Cambridge) to a Mr. and Mrs. John Jaffe Donation Studentship to carry out research on the structural studies of intermetallic compounds at the Crystallographic Laboratory, Cavendish Laboratory, Cambridge; Mr. J. R. Cross (University College, Swansea) to a Mr. and Mrs. John Jaffe Donation Studentship to carry out research on the physical chemistry of cell processes at the Physical Chemistry Laboratory, University of Oxford; Dr. J. E. Falk (University College Hospital Medical School) to a Foulerton Research Fellowship to carry out research on the biochemical mechanisms involved in the production of porphyrins and hæmoglobin by animal tissues at University College Hospital Medical School, London; Dr. P. M. Holton (*née* Watson-Williams) (Physiological Laboratory, University of Cambridge) to a Foulerton Research Fellowship to carry out research on chemical transmission in the nervous system at the Physiological Laboratory, University of Cambridge; Mr. A. E. Litherland (University of Liverpool) to a Rutherford Memorial Scholarship to carry out research on fast-neutron spectroscopy at the Atomic Energy of Canada, Ltd., Chalk River, Canada (the financial provision for this Scholarship is being made by the Atomic Energy of Canada, Ltd., with whose agreement the Council of the Royal Society has conferred on Mr. Litherland the title of Rutherford Memorial Scholar); Mr. B. J. Robinson (University of Sydney) to a Rutherford Memorial Scholarship to carry out ionospheric research at the Cavendish Laboratory, Cambridge.

Paris Academy of Sciences: Recent Elections

THE following elections have been made in the Paris Academy of Sciences: Prof. L. Néel, professor of experimental physics in the University of Grenoble, to be non-resident member in succession to the late Prof. J. Haag; Prof. L. Escande, director of the Institute of the Mechanics of Fluids, University of Toulouse, to be *correspondant* for the Mechanics Section in succession to Prof. J. Leray, recently elected member of the Section; and M. A. Coutagne, consulting engineer, to be *correspondant* for the Section of Geography and Navigation in succession to the late Sven Hedin.

Presidency of the Institution of Mining Engineers: Major N. E. Webster, O.B.E.

MAJOR NOEL E. WEBSTER has been elected president of the Institution of Mining Engineers for 1954–55 and will succeed Prof. J. Cecil Mitcheson at the sixtieth annual general meeting of the Institution, to be held in London on January 28, 1954. Major Webster, who was born in 1893, received his early training at the then University College, Nottingham, and obtained his colliery manager's certificate in 1919. During the First World War he gained first the M.C. and later the O.B.E., this latter being awarded for his services in connexion with the development of sound-ranging and flash spotting for counter-battery fire. He was for many years managing director of the Nunnery Colliery and associated companies, where he was concerned with the development and early application of mobile coal-getters for working under Sheffield. At present he is chairman of several companies connected with equipment for mine-working and the utilization of coal, and is associated with many other concerns in these lines. As one who conducted research on strata control and on the application of electrical power to mining practice, Major Webster is naturally keenly interested in the training and education of mining engineers, and, among his services in this field, he is chairman of Sheffield University Mining and Fuel Committee.

The Smithsonian Institution: Mr. Andrew Kramer

Mr. Andrew Kramer, the instrument-maker, who has produced some of the most precise instruments known to science, retired from the Smithsonian Institution, Washington, after sixty-one years service. He joined the Institution in 1892 and then worked with S. P. Langley on the latter's famous aeroplane and the models which preceded it. After that he always remained associated with the Institution's Astrophysical Observatory which was founded by Langley. Some of Abbot's well-known pyrheliometers and pyranometers, constructed by Mr. Kramer, and designed to measure extremely fine differences in solar heat radiation, are sufficiently sensitive to measure accurately the heat of a candle twenty miles away. Mr. Kramer was not merely an instrument-maker, for he understood the theory and purposes of all the instruments he made, and often suggested steps to increase their precision. His *magnum opus* was the chamber for Abbot's water-flow pyrheliometer. Mr. Kramer is eighty-four years of age. Men of science will wish him and Mrs. Kramer happiness during his retirement.

Hilda Martindale Educational Trust for Women

By the terms of the will of the late Miss Hilda Martindale, an educational trust has been set up, with capital amounting to £30,000, which will be administered by trustees appointed by Bedford College, London. The income will be used to help "girls and women of the British Isles intending to fit themselves for some profession or career, likely to be of use or value to the community, for which special training is required". Medicine, nursing, agriculture, architecture, engineering, posts in the higher grades of the Civil Service and inspectorships are some of the careers cited by Miss Martindale in her will as examples of what she had in mind. Miss Martindale's life was one of continual social service, and she was particularly interested in the welfare of children, especially in regard to the work of juvenile courts and orphanages. Educated at Royal Holloway College, London, the Royal Sanitary Institute and Bedford College, her first post was in 1901 as a factory inspector in the Home Office, and in the Civil Service she rose to become deputy chief inspector of factories and then, from 1933 until her retirement in 1937, director of women's establishments for the Treasury. After she had retired, Miss Martindale was able to devote more of her time to her two great interests—the Friendly Almshouses, founded by her great-grandmother, and Dr. Barnardo's Homes.

The Wilfred Hall Telescope

Fears which had earlier been expressed regarding the future of the 15-in. twin astrographic telescope left by the late Dr. Wilfred Hall to the Royal Astronomical Society were dispelled by the president of the Society, Dr. John Jackson, at its summer meeting in Newcastle on July 22. The Society could not have accepted the bequest, under the terms of the will, unless the telescope could be re-erected at some place at which it could be used for scientific research. The testator's intentions will be complied with by a long-term loan of the instrument from the Society to the municipality of Preston, Lancashire, which already manages the Jeremiah Horrocks Observatory. Support from the Ministry of Education will enable the telescope to be re-mounted at Preston, where, it is hoped, it will shortly enter upon a new lease of useful life.

Use of Peat for Gas Turbines in Scotland

In the course of a debate in the House of Commons on Scottish affairs on July 14, the Secretary of State for Scotland, Mr. James Stuart, stated that the report of the committee, under Sir Edward Appleton's chairmanship, which has been investigating the possibility of developing Scottish peat deposits, is in an advanced stage of preparation. Meanwhile, a specific recommendation of the committee, supported by Sir William Stanier's gas turbine committee, that the North of Scotland Hydro-Electric Board, with assistance from the Development Fund, should set up an experimental peat-burning power station at Altnabreac, Caithness, has been accepted by the Development Commissioners and the Treasury. The plant will consist partly of a 2,000-kW. closed-cycle gas turbine on which the North of Scotland Hydro-Electric Board and Messrs. John Brown and Co., of Clydebank, have been working since 1947. An oil-burning turbine of this type, the first in Great Britain, is expected to be in operation at Carolina Port, Dundee, in three or four months time. A pilot gas turbine burning dried peat has also run for a thousand hours at Clydebank with promising results, and the new peat plant is a development of this. In addition, the scheme will include a 750-kW. open-cycle turbine built to the order of the Ministry of Fuel and Power out of a grant from the Development Fund, which will be installed as soon as it has completed the necessary tests and is in full working order. The whole pilot scheme will take three to four years to complete, and the capital and development costs, estimated at about £500,000, will be met mainly from the Development Fund with contributions from the Hydro-Electric Board and the British Electricity Authority. If the scheme is successful, it is the intention of the Hydro-Electric Board to proceed to larger schemes on other suitable areas in the Scottish Highlands. It is estimated by the peat committee that about 600 million tons of peat solids are available in Scotland, in areas where depth, accessibility and other features make them suitable for utilization, and, of these, about 130 million tons are in Caithness and Sutherland.

Humicolin, a New Antibiotic

It has been shown by P. J. Curtis, H. G. Hemming and E. G. Jefferys that *Aspergillus humicola*, a fungus obtained from soil in deep caves, produces an antifungal substance to which the name humicolin has been given (*Trans. Brit. Mycol. Soc.*, **35**, Part 4, 263; December 1952). The substance is obtained by extraction of culture filtrates with charcoal, from which it is eluted with carbon tetrachloride. It is a weakly acidic yellow oil, soluble in petrol ether, contains no nitrogen, sulphur or halogen, but probably has a phenolic or enolic group; it crystallizes from methanol at − 80° C., distils at 210–215° C. at 10^{-4} mm. of mercury, is moderately stable in aqueous solution at *p*H 3·5–4·5, but is inactivated at higher *p*H values. Humicolin inhibits the spore germination of several common fungi—at concentrations ranging from 0·4 μgm./ml. for *Fusarium caeruleum* to 12·5 μgm./ml. for *Trichoderma viride*, though spores of *Absidia glauca* are not prevented from germinating by 50 μgm./ml.

Radioactive Cortisone and Hydrocortisone

A limited supply of radioactive cortisone and hydrocortisone is now available without charge to qualified investigators through funds supplied by the National Institute of Arthritis and Metabolic Diseases, Public Health Service. Both are labelled at position 4 with carbon-14. The cortisone has a specific activity of 0·49 mC./m. mole, and the hydrocortisone a specific activity of 1·47 mC./m. mole. Requests, in the form of a letter concisely describing the proposed research, should be sent to the Division of Research Grants, National Institutes of Health, Bethesda 14, Maryland, U.S.A. Transfer and use of these materials are subject to current regulations of the U.S. Atomic Energy Commission. Synthesis of these ring-labelled compounds was an international co-operative effort: the United States Atomic Energy Commission supplied the radiocarbon; Charles E. Frosst and Co., of Montreal, synthesized the radiocortisone, with help from the Upjohn Company; the Worcester Foundation, utilizing radioactive progesterone prepared by Frosst, prepared the hydrocortisone by biosynthesis.

University of Leeds

Dr. R. D. Preston, reader in plant biophysics in the University, has been appointed professor of plant biophysics in the Department of Botany as from October 1.

Dr. W. A. Sledge, lecturer in botany, has been granted leave of absence for the second term of session 1953–54, to enable him to continue researches on the fern flora of Ceylon.

The following gifts have been received: for the Clothworkers' Departments, £1,550 for 1952–53 from Courtaulds, Ltd., to be used as follows—£700 for scholarships, £600 for research in the Department of Textile Industries, £250 for research in the Department of Colour Chemistry and Dyeing; for the Department of Inorganic and Physical Chemistry, £1,500 from the Department of Scientific and Industrial Research for crystallographic computations on the electronic computer at the University of Manchester.

Swiss Society for Natural Sciences

The Swiss Society for Natural Sciences will hold its 133rd annual meeting at Lugano during September 5–7, under the presidency of State Councillor Dr. B. Galli. Medical biology will again be to the fore, with a general session on radioactive isotopes, and so will medical psychology and psychiatry with a historical session. Prof. A. Lombard, of Brussels, reporting on his 1952 Everest Mission, and Prof. G. Polvani, of Milan, speaking about Volta's notes on a journey through the St. Gotthard, will interest a general audience. The supporting section programme is fullest in chemistry, with speakers from Heidelberg, Marburg, Milan, Boston and Philadelphia. A notable communication announced in the combined programme for geophysics, meteorology and astronomy is one on echosondage of the atmosphere by Prof. J. Lugeon, of Zurich. Botanists will discuss polyploids with the zoologists and geneticists. The meeting will be followed by a visit to the electric generating station in the Valle Maggia, a botanical excursion to the Isola di Brissago, and extensive geological tours.

Announcements

We regret to announce the death on July 26 of Dr. M. H. Gordon, C.M.G., C.B.E., F.R.S., consulting bacteriologist at St. Bartholomew's Hospital, London, aged eighty-one years.

The Society of Dyers and Colourists has elected Mr. J. G. Hopkinson to be honorary secretary in succession to Mr. J. Barritt, who has resigned owing to the pressure of other commitments. Mr. Barritt will, however, continue as chairman of the editorial panel and serve the Society in other branches of its work dealing with publications. Mr. Hopkinson, who is a graduate in chemistry of the University of Oxford and has studied dyeing and textiles at the University of Leeds and Bradford Technical College, is a director of Hopkinson and Shore, Ltd., dyers and finishers of Brighouse, Yorks.

A Glaxo Laboratories Research Fellowship has been granted through the Friends of the Hebrew University to Miss Alisa Tietz, a graduate of the Hebrew University of Jerusalem, who is at present doing research in the Biochemistry Division of the Medical Research Council in London under Dr. A. Neuberger.

According to a written statement made in the House of Commons on July 15 by the Secretary of State for the Colonies on the subject of technical officers in agricultural departments of Colonial Territories, out of a full establishment of 1,270 officers serving an area of more than 25,000 square miles the number of vacancies known to the Secretary of State is 122. Seventy-seven candidates have been selected but are still in training, leaving forty-five vacancies still unfilled.

The triennial award of the Coopers Hill War Memorial Prize and Medal has been made by the Institution of Electrical Engineers to Mr. G. Lyon, for his paper on "Some Experience with a British A.C. Network Analyser". The Coopers Hill War Memorial Prize, which was founded by the members of the Royal Indian Engineering College, Coopers Hill, in commemoration of members of the College who fell during the First World War, is awarded annually by the Institution of Civil Engineers, and triennially in turn by the Institution of Electrical Engineers, the School of Military Engineering, Chatham, and the School of Forestry, Oxford. It consists of a bronze medal, a certificate and about £20 in money, and is given for the best paper on a professional subject published by the Institution during the period concerned, the award being restricted to corporate members less than thirty-five years of age.

MOLECULES OF WATER IN SOLIDS

A CONFERENCE was held in Paris during June 24–26 under the auspices of the Centre National de la Recherche Scientifique, supported by the Rockefeller Foundation. The conference was the fifty-third in the series of discussions organized by the Centre National, and, as in previous conferences, it was limited to about twenty specialists. The full title of the discussion was "The Study of Molecules of Water in Solids by means of Electro-Magnetic Waves (from X-Rays to Radiofrequencies)". All the meetings except the last were held in the Institut de Chimie-Physique, of the Sorbonne, Paris, and the last session was held in one of the laboratories at the Château Gif. The following topics were discussed: (a) crystal structure and the physical properties of hydrates; (b) dielectric constants and dielectric absorption as a function of frequency and temperature; (c) infra-red spectra due to H_2O and OH groups; (d) Raman spectra; (e) magnetic resonance.

The papers presented at the conference showed that considerable advances are being made in the study of the water molecule in crystalline hydrates. Among the new techniques should be mentioned nuclear resonance and Raman spectra. The interaction of the protons within each water molecule makes it possible to determine, with a precision of a few degrees, the direction of the line joining the protons. Magnetic resonance measurements can also frequently afford a reasonably accurate measure of the distance apart of the protons. However, no information can at present be gained by this method concerning the relative positions of the oxygen and hydrogen atoms within any one molecule. Even with this limitation, the new method is complementary to the methods of X-ray crystallography, which are primarily useful in fixing the position of the oxygen atoms. The frequencies of the Raman spectra are determined by the modes of vibration of the water molecule and the polarization of the Raman lines by the orientation of the molecule. When the mode of vibration can be identified by the frequency and when the crystal structure is not too complicated, it is possible to determine the direction of the OH bonds. This, too, is information complementary to that obtainable by X-rays. A present limitation on both these methods is the large size of crystal required.

The advances made using the older methods are due to the greater detail in the information available. For example, ninety-six crystal structures of hydrates have been established, and it has therefore become possible to devise a classification of hydrate structures based on the clustering of the water molecules into island-like, fibre-like, leaf-like or cage-like arrangements. To cover these categories the words neso-, ino-, phyllo-, and tecto-hydrates have been adopted from the earlier classification of the silicates. This classification brings out the variation in the way the water is included in the structure—a variation extending from practically free water, through hydroxyl and/or hydrogen bonds, to the oxonium ion.

The dielectric constant and dielectric absorption as functions of frequency and temperature have been extensively studied, though it must be said that the results do not lead to any fundamentally new information. Relaxation time and energy of activation can often be determined; but the dynamics of the water molecule in crystalline hydrates are still beyond adequate mathematical treatment.

Numerous infra-red spectra, both of powders and of single crystals, in polarized infra-red radiation have been studied. Bands of absorption or selective reflexion can be identified in many hydrates with the type of binding of the water molecule present. The influence of the surrounding ions can be traced in the changes in frequency and band-width. Like the studies on dielectric properties, the infra-red properties are often of considerable industrial importance, in determining the amount and kind of binding of the water present.

Lastly, enough information has become available to make possible some correlation of the crystal structure of hydrates with their coefficients of thermal expansion, dielectricity, piezoelectricity, elasticity and hardness.

It is intended to publish the papers presented to this conference in a forthcoming number of the *Journal de Chimie Physique*.

The following is a list of the authors and the titles of their contributions:

X-rays and physical properties. J. D. Bernal (London), "The role of water in crystalline substances"; P. G. Owston (London), "The position of the hydrogen atoms in ice"; W. A. Wooster (Cambridge), "The influence of molecules of water on the physical properties of crystalline hydrates".

Dielectric constants. R. Freymann (Rennes), "Absorption of free and bound water in Hertzian spectra"; "Orientation of molecules and lattice defects"; E. Bauer and M. Magat (Paris), "Dispersion of the dielectric constant in crystal hydrates"; J. B. Hasted (London), "Study of water molecules at radio frequencies"; A. Steinemann (Zurich), "Dielectric constant of ice"; J. Chapelle and A. Galy (Nancy), "Dielectric constants of some crystal hydrates"; P. Abadie, R. Charbonniere, A. Gidel, P. Girard and A. Guilbot (Paris), "Study by absorption spectra at radio frequencies of water in the crystallization of maltose and glucose and study of the states of water of sorption in 'amidon'".

Infra-red spectroscopy. J. Lecomte (Paris), "The study of water in solids by infra-red spectra"; R. Mecke (Freiburg-im-Breisgau), "Detection of OH in crystals by infra-red spectroscopy"; D. E. Bethell and N. Sheppard (Cambridge), "Infra-red spectra of nitric acid monohydrate"; A. M. Vergnoux (Montpellier), "Infra-red studies of the OH bands in crystals".

Raman spectra. J-P. Mathieu (Paris), "The Raman effect in hydrated crystals"; L. Couture-Mathieu (Paris), "The Raman effect in gypsum"; R. Lafont and Ch. Bouhet (Montpellier), "The water-bands in single crystals of magnesium and zinc sulphate heptahydrates"; C. Vassas-Dubuisson (Paris), "The Raman effect in a single crystal of lithium sulphate monohydrate"; J. Chapelle and A. Galy (Nancy), "Attempt at orientation of the molecules of water in hydrated crystals by means of the Raman effect"; J. Chapelle, G. Champier and C. Delain (Nancy), "Interpretation of the Raman spectra due to water molecules in Rochelle Salt".

Nuclear magnetic resonance. G. E. Pake (Washington University, Miss.), "Application of nuclear magnetic resonance to the study of the structures of crystals containing molecules of water"; M. Soutif and Y. Ayant (Grenoble), "Study of the water molecule in lithium sulphate monohydrate"; N. J. Poulis and G. E. G. Hardeman (Leyden), "Position of protons in $CuCl_2.2H_2O$ determined by the method of nuclear magnetic resonance"; W. Gordy (U.S.A.), "The spectra of water vapour in the millimetric range". W. A. WOOSTER

INTERNATIONAL ELECTRO-ACOUSTICS CONGRESS

AN "International Electro-acoustics Congress" was held in Holland during June 16–24. The congress, which was organized by a Dutch Committee, presided over by Prof. C. W. Kosten, was the first venture sponsored by the newly formed International Committee of Acoustics (I.C.A.), an offshoot of Unesco. It was held in the main at the Technische Hoogeschool, Delft, and was attended by more than three hundred people, representing many countries.

After addresses by the president of the Congress, H. E. the Minister of Education and Prof. R. H. Bolt, president of the International Committee of Acoustics, the Congress settled down to hear general reviews of progress in the seven sections into which the subject had been divided. These are summarized below.

Section I: Sound Recording. R. Vermeulen described improvements which have been made in disk and tape recording. He pointed out the need for defining standards in reproduction apparatus. Frequency response is not the only criterion; the psychological attitude of the hearer and the auditorium in which he listens play a large part in appreciation. Advances in stereophony were pointed out and—later in the Philips works—a two-channel demonstration was given to show that the illusion of space in such a system is still imperfect.

Section II. Public Address Systems. Erwin Meyer pointed out that the loud-speaker remains the weakest link in this type of transduction, which has become so important in modern life. Usually it is more important, at least in speech, to get the high frequency amplified than the bass. Different types of microphones and arrays of loud-speakers were described, and the advantages of delay pick-ups as used in St. Paul's, London, for large auditoria was explained.

Section III: Measurements. L. Beranek emphasized the need for measuring devices which include the listener as part of the system. This science of psycho-acoustics is still in its infancy; but many acoustic measurements are valueless without it. On the purely physical side, the most important developments are in high-frequency microphones for use in a wide range of conditions, in the measurement of acoustic and mechanical impedance.

Section IV: Audiometers. P. Chavasse also pointed out the need for listener research in this field, which should cover not only psychological reaction but also measurements of a more physical character like the impedance of the external ear, diffraction of sound by the head, artificial ears, and establishment of a norm of hearing for all countries.

Section V: Ultrasonics. G. Bradfield described recent advances in transducer design for this range, now going up to 3,000 Mc./s., particularly those involving barium titanate and the ferrites. Transducers for pulse excitation using Rochelle salt or long nickel tubes with the distant end immersed in grease have also been used in delay lines, while for ultrasonic cutting tools, 'Permendur' is used. The characteristics of many of these were discussed through their equivalent circuits or Argand diagrams. More study is needed of the launching of waves in solids, where the energy tends to be transferred to and from transverse and longitudinal waves, complicating the process.

Section VI: Musical Acoustics. E. G. Richardson described the benefits which this branch has derived from advances in electrical tone synthesis. Recent research has shown the importance of a knowledge of the formants (varying timbre over the scale) and transients of musical instruments in differentiating them and assessing their relative excellence. Work on the violin and the organ-pipe in particular was described.

Section VII: Lightweight Structures. C. W. Kosten pointed out the difficulties in building an insulating wall between two rooms without excessive weight. Flexural stiffness and resistance must be introduced to compensate for the light weight, and resonances must be distributed over the gamut. Both cavity walls and filled double-wall structures are employed.

After this the Congress divided into Sections, in each of which ten to a dozen papers were read, that of Section VI being enlivened by demonstrations on various musical instruments varying from bagpipes to just-tempered organs.

On two days visits to Hilversum Radio and Philips Industries, Eindhoven, were made.

EUROPEAN ASSOCIATION OF EXPLORATION GEOPHYSICISTS

PARIS MEETING

THE fourth meeting (second annual meeting) of the European Association of Exploration Geophysicists was held in Paris during May 20–22, when about a hundred and fifty members were present, the president, A. van Weelden, being in the chair. Membership now stands at more than five hundred and fifty, a remarkable achievement since the Association's inauguration in December 1951. Affiliation with the Society of Exploration Geophysicists (U.S.A.) has recently been approved, and a paper entitled "The Significance of Diffraction in the Investigation of Faults"[1] by T. Krey, presented at the Association's meeting in London in May 1952 and published in the *Journal* of the Society of Exploration Geophysicists (before the Association's own journal, *Geophysical Prospecting*, was in being), has received the Society's award for the best paper during 1952.

In his presidential address, A. van Weelden discussed the various ways in which the results of gravity surveys are analysed, and emphasized the imperfections and ambiguities in the interpretations which are brought about by unjustified assumptions. In this regard, he stressed the necessity for close co-operation between geologist and geophysicist, a necessity which is sometimes not given full support.

Of the twenty-two papers presented at the meeting, seven were on seismic, six on electrical, four on magnetic, two on gravity and three on general problems in exploration geophysics.

The interpretation of reflexion records obtained over fault zones is receiving much attention by workers in oil-field exploration, as oil may be found in stratigraphic traps up against the fault face, and in a paper by K. H. Seelis (Germany) the diagnostic features such as character of reflexion, abnormal dips, displacement of the reflected arrival and a variation of the velocity/depth distribution in crossing a fault were exemplified by records and depth sections. The last feature was also discussed in a paper by H. A. Rühmkorf (Germany), who noted that the travel times from a well geophone to two surface geophones equidistant, but in opposite directions, from the well differed by a small amount (0·01–0·02 sec.). It was pointed out in the subsequent discussion, however, that care must be taken to eliminate any time differences due to an uneven thickness of the very low velocity (2,000 ft./sec.) near-surface beds.

In computing depths to the reflecting bed, the normal procedure is to employ an average velocity; but this only holds for small dips. When the geological layers are much inclined, some allowance must be made for varying layer velocities, and H. Dürbaum (Germany) presented formulæ for the direct determination of them from the records; he also discussed the errors introduced by assuming average velocities in such cases. An interesting account of reflexion investigations in the Swabian Molasse basin in front of the Bavarian Alps was given by W. Elberkirch (Germany). Here the erratic glacial drift is largely responsible for the paucity of the reflexions; but the top of the Mesozoics appears to offer a useful key horizon, the deepest part of the Tertiary basin holding an estimated 10,000 ft. of sediments.

H. Menzel (Germany) described laboratory studies of the propagation of elastic waves in a solid with elastic afterworking. He found that high-frequency waves are not absorbed as is the case in visco-elastic theory, and considered that some modification of the latter theory in accounting for the shapes of seismic onsets is desirable.

All seismic workers are familiar with graphical methods of constructing depth-sections, but the conversion of a time-section when the velocity is not constant leads to refraction complications across the various seismic layers. To obviate lengthy computations, however, J. Dienesch and H. Richard (France) have evolved and presented geometric constructions in reflexion problems of this kind.

A most informative paper on explosives in seismic prospecting by S. H. Davidson, R. Westwater and J. Hancock (Great Britain) brought the seismic session to a close. Chemical stability, freedom from grit contamination and transportation and preparation of the explosive for lowering into the shot-hole were all discussed. In order to lessen the hazards in operation, a new explosive, 'Seismex', with an ammonium nitrate base, has been produced in recent years by Imperial Chemical Industries, Ltd., but owing to its hygroscopic nature it is cased in water-tight tins; it suffers the disadvantage, however, of not being able to stand up to the great pressures sustained by the nitroglycerine explosive, 'Geophex', which is capable of exploding under a water pressure of 1,000 lb. per sq. in. In the following discussion, some interesting observations were made on sympathetic explosions of a second buried charge situated a short distance from, and on firing, the first; methods for distinguishing between the sweating of nitroglycerine and the presence of water particles on the explosive surface in tropical climates were also described.

Geophysics is playing an increasing part in the coal mining industry, and the National Coal Board of Great Britain has a wide programme of research on problems affecting the safety of the mine and mine-worker from subsidence of unconsolidated strata and a waterlogged overburden. In a paper by G. M. Habberjam and J. T. Whetton, an account was given of a resistivity investigation into an old river valley in Coal Measure strata, the trend of the valley being completely delineated. A second paper by E. Jan Polak described the attempt to demarcate the freshwater Trias formations from the brackish Coal Measures; but lack of homogeneity in electrical properties of the rocks resulted in a rather indefinite boundary. The exploration for water by (*a*) electrical and (*b*) seismic refraction methods in the desert areas of Mauritania (Morocco) was discussed in an interesting paper by J. J. Breusse and G. Huot (France). Close agreement between the thicknesses of the clay-sandstone complex resting on a crystalline basement was found by the two methods, while it was also found possible to distinguish between fresh and saline water areas. Six drill holes put down afterwards corroborated the general results of the surveys.

The important branch of electrical surveying which has to do with measurements in bore holes was represented by three papers. The first, by A. P. Poirault (France), reviewed the development of gamma-ray logging, micro-logging and side-wall sampling as applied to holes drilled for minerals other than oil, and described the results obtained in the case of coal seams in England, lignite deposits in the Cologne basin and the potash beds in Alsace. A second paper, by I. Wendt (Germany), discussed a method using two counting tubes for determining the radioactive potassium in thin deposits, while a third paper, by L. Solaini (Italy), gave an account of an instrument for measuring resistivity with alternating current at 20 c./s.

In the magnetic section a paper by S. Matweber and K. Jung (Germany) described how a reasonable interpretation of a very detailed vertical intensity survey (station interval 30 ft.) in the Red Iron district of Lahn and Dill attributed some small-size anomalies of large magnitude to a variable magnetic content of underlying diabase. On drilling, however, iron ores rich in magnetite were penetrated at shallow depth before basement was reached. In discussion, it was agreed that measurements of the vertical gradient of intensity by means of observations on elevated platforms would lead to a nearer estimate of the depth to the magnetic disturbance. F. Sumi (Yugoslavia) introduced a somewhat academic note when he discussed the magnetic anomalies to be expected from spheres and cylinders, and A. Lundbak (Denmark) reviewed the limiting factors in airborne magnetic surveys and referred to some recent modifications of the fluxgate magnetometer. Most workers with the vertical magnetometer of the Schmidt type believe that constructional errors are eliminated by taking the mean of magnet readings in azimuths 180 degrees apart; but J. McG. Bruckshaw (Great Britain) demonstrated that, as the inclination of the knife edge is fixed by an arbitrary setting of the levels, elimination of errors due to this inclination and to misorientation is incomplete. Formulæ permitting the determination of the tolerance in knife-edge tilt and azimuth in any particular case were given.

C. Aynard (France) presented a paper on the interpretation of the gravity results obtained in the Gharb basin of Morocco and compared them with the known geology and the results of seismic and electrical surveys; it appeared that most of the local gravity features are related to the pre-Riff tectonics. In precision gravity surveys, corrections are made for diurnal variation, and C. Morelli (Italy) explained that the determination of the diurnal variations for northern Italy now being effected at the Geophysical Observatory, Trieste, can be extended with slight modifications to almost the whole of Europe, the work being facilitated by the use of nomograms. In the following discussion it was agreed that the Council should consider the appointment of a committee to study this important matter.

Papers which compare the results of various surveys in the same area are particularly stimulating, and such was the case when A. M. Selem and C. Monnet (Italy) gave an account of the seismic reflexion, telluric and gravity surveys in the Ferrara area of northern Italy, where an early torsion-balance survey had indicated a broad uplift in the Tertiary and Mesozoic formations. A broad agreement was shown to exist among the results given by the three methods. A further comparison was made by means of the derived vertical gravity-gradient (using Baranov's formula presented at the previous meeting of the Association in Hanover) in the area where reflexions were poor; agreement with the telluric results was marked. Geological data from two wells drilled to 1,300 ft. and nearly 2,100 ft. over the uplift tended to support the geophysical conclusions.

The degree of certainty of the interpretation of geophysical results was discussed in a paper by M. Matschinski (France). Here the problem was divided into four parts: (a) mathematical description of a hypothetical geological structure satisfying the geophysical data; (b) determination of the parameters defining the structure; (c) the likelihood that these parameters are the only ones; and (d) determination of the likelihood of the hypothesis itself. The necessity for accepting some limitation for parameter variation was discussed, and applications of the general theory to seismic and gravity measurements were given.

The technical session closed with a paper dealing with safety regulations in geophysical prospecting by H. Richard (France) and the showing of a 'Technicolor' film entitled "Make no Mistake" (presented by courtesy of Geophysical Service Incorporated, U.S.A.). These provoked considerable discussion, and it was agreed that a special committee be formed to consider and make recommendations on this very important subject.

It is to be regretted that spoken language difficulties were emphasized by the almost complete lack of copies of the various papers. Abstracts were not available to members until just before the meeting, so that even if the speaker's language was understood, there was little or no time for a member to consider carefully the points brought out in a paper with the view of joining in the discussion. It is to be hoped that copies of the papers for the next meeting, probably in Italy, will be circulated well in advance, so that it would only be necessary for the speaker to dwell on the salient or controversial parts of his subject in a relatively short time, thus leaving a much desired longer time for the discussion.

Some very informative exchanges of experiences and ideas were made between members outside the lecture theatre, and this more personal contact is obviously a most attractive feature of the meetings. The Compagnie Générale de Géophysique and the Société de Prospection Electrique kindly made all the arrangements for the meeting, which included several enjoyable sight-seeing tours for members' wives.

The following officers were elected for 1953–54: *President*, D. T. Germain-Jones (Great Britain); *Past President*, A. van Weelden (Holland); *Vice-President*, J. Goguel (France); *Secretary/Treasurer*, B. Baars (Holland); *Members of Council*, A. Schleusener and F. Werner (Germany), J. L. Mathieu (France), T. Rocco (Italy), J. McG. Bruckshaw (Great Britain) and D. Malinqvist (Sweden).

T. C. RICHARDS

LIBRARY FACILITIES IN THE UNITED STATES

AMONG the papers presented to the Library Association at its annual conference at Llandudno during April 28–May 1, that of Mr. R. W. L. Collison on aspects of co-operation in university and special libraries in the United States of America appears to be the one of most interest to scientific workers or technologists as such. Mr. Collison began by referring to the awareness of librarians in post-war America of the need for the closest co-operation between all types of libraries, particularly between those libraries which are in any way concerned with the advancement of research and scholarship, and to the extent to which practical co-operation between university and special libraries has already developed in the United States. Even many American librarians, however, are unaware of the full implications or of the general pattern. Much has been achieved, for example, by the wide exchange of catalogue entries between university and special libraries interested in the same subject or group of subjects. From this it is but a short step to the co-operative planning of book purchase, such as the long-standing agreement between the John Crerar Library, the Chicago Public Library and the Newberry Library as to which subject-fields each will cover. Book- and serial-withdrawal has become a fruitful field for extensive co-operation, and the establishment of the Mid-West Inter-Library Centre in which, besides university libraries, the Illinois Institute of Technology and the John Crerar Library are co-operating, has led to substantial economies as well as to the filling of important lacunae.

There is no inter-loan system as comprehensive as that established in Great Britain, continued Mr. Collison; but some bibliographical centres have developed their services further than any single regional bureau in Britain. Almost every field of research in the area has availed itself of the services of the Philadelphia Centre, and important industrial libraries are co-operating. The scale of assistance of university libraries to special libraries in the United States is unequalled in any other country, and the universities in the United States usually pay much attention to local industries and professions. Organizations on both sides are very willing to exchange publications, while the universities often undertake important schemes of research on behalf of Federal, State, or private bodies in return for considerable grants of money to cover the costs involved, thus often strengthening the holdings of the university library in subjects where it was weak. Mr. Collison went so far as to suggest that this strong link between commerce, industry and the university helps informally to direct research material to the most appropriate library. He also pointed out that in the United States the membership of most university libraries is almost unrestricted, provided a serious purpose is proved, and special libraries have little hesitation in approaching university libraries for help and for the loan of books, reciprocating by admitting readers recommended by the universities.

On the national scale the wise guidance of the Library of Congress can be seen in all aspects. The work of this Library in co-ordinating the efforts of all types of libraries is invaluable: its bibliographical aids were evident in every research library, and in return it does not hesitate to call on libraries with specialist knowledge to assist in the preparation of catalogue cards, bibliographies, etc., of specialist material. Besides the Farmington Plan, which has been revised so that the coverage of subjects is reduced to a much smaller number of libraries, while government publications are now included, there is the war-time scheme of the Library of Congress for obtaining for research libraries books and periodicals published in enemy countries and a similar scheme for Russian material. The National Union Catalogue contains entries for about fifteen million items in research libraries of all types, and inter-library book exchange is helped by extraordinarily low postage-rates. An important development has been the establishment of the Association of Research Libraries, comprising some forty leading libraries in the United States, and the considerable amount of informal co-operation between university and special libraries can be extended formally and informally without major alterations in the policy of either type of library. There is now contemplated the transfer to a regional library created for the purpose of extra-local responsibilities which local research libraries more and more find themselves bearing.

EXCAVATIONS AT MARGIDUNUM

In his latest report[1], Dr. Felix Oswald continues the story of his work at Margidunum with an account of the area in the southern half of the site extending from the *Via Quintana* to the Counterscarp. This includes the site of the southern rampart with various pits and wells, and the first four outer ditches, as well as the smaller outer ditches V and VI which outline a paved patrol path for sentries placed along the Counterscarp. The Insula containing the Commandant's House, described in an earlier account in this series[2], lies immediately to the north of these features, on the other side of the *Via Quintana*.

The present report is chiefly concerned with the pottery and other objects found, the material being illustrated by a series of plates, each accompanied by a description of the individual items. The rest of the text is devoted to further description and discussion; but unfortunately this is marred by several unlucky misprints, for example, on p. 6, Plate IX in the second paragraph should read Plate VII, and XIII on p. 8 should always be replaced by a XII. The earliest finds, those dating from the mid-first century A.D., come from ditch 5 beside the *Via Quintana*, and ditches 9, 10 and Z. As well as some unusual Terra Sigillata, they include interesting examples of butt beakers, rusticated and green glazed wares, and storage jars. Of slightly later date is a grey urn with a pronounced cordon below the neck with four *appliqué* hares seated upon it, an attractive discovery found in the lower levels of one of the stone-lined wells. Iron ore and slag came from some of the pits in the area demarcated by ditch 10, and these were obviously used for smelting; they were straight-sided and resemble pits used for similar purposes in parts of Africa. Another pit, near the junction of ditches 9 and 10 this time, contained the skeletons of six large dogs, probably injured in wild boar hunts in the nearby forest.

Towards the end of the first century, ditch 10 seems to have been used as a foundation trench for one wall of a building, identified as a stable after the excavation of pits in this area containing horse dung (still fresh), yellow straw, twigs and other stable litter, preserved from decomposition by a sealing layer of clay. The later history of the site is represented by some second-century pottery from the outer ditches, and the contents of the third century well already described in an earlier publication[3]. Pottery of the third and fourth centuries was also found in outer ditch III, while outer ditch I was partly obliterated by a late fourth-century wall.

AEROPLANE OBSERVATIONS OF HOMING PIGEONS

The homing of domestic pigeons and the migrations of wild birds are often considered as comparable cases of natural navigation. In both types of long-distance flight it is difficult to discover adequate guiding cues that lie within the sensitivity range of the birds' sense organs.

Direct observation from aeroplanes has recently thrown some light on the actual routes which wild birds use in finding their way home to their nests after being artificially transported to a distance. Herring gulls and gannets were observed to make exploratory flights in many directions, flights which covered a wide area surrounding the release point and which probably brought the birds, in time, within sight of familiar landmarks. It therefore seemed desirable to apply to pigeons the same technique of aeroplane observation which had been developed for use with wild birds, and this has been done by Donald Griffin (*Bull. Mus. Comp. Zool.*, 107, No. 8; December 1952).

Fifteen observation flights over distances up to a hundred miles disclosed several cases in which the birds appeared to be relying upon exploration or topographic landmarks. In other instances there was a definite tendency for the pigeons to head in the approximate direction of home, even when flying over what was almost certainly unfamiliar territory. Despite the fact that no final conclusions can be drawn from the results of these observations, the homing behaviour of these pigeons is of interest in view of the scarcity of precise, adequately controlled descriptions of the actual routes between release points and home loft.

From this investigation and those of other workers, Griffin concludes that it is advisable to distinguish three distinct levels of navigational ability. What may conveniently be called type I homing is reliance upon "contact flying" within familiar territory. When released in totally unfamiliar territory, birds which exhibit only type I homing show a quantitative homing performance that can easily be accounted for by theories of exploration or even by a completely random search for familiar landmarks. They may be misled by topographic features resembling portions of their familiar territory.

A second level of homing, conveniently designated type II, is the ability to maintain flight in roughly a fixed direction, usually that adhered to in previous training flights.

There is also a third level of homing ability, conveniently designated as type III, which permits birds to fly approximately straight towards home from unknown territory regardless of the direction in which home lies.

While differentiating between these three types, the same flock of pigeons may exhibit two, or even all three, of these types of orientation at different times during a single homing flight.

Finally, it must be admitted that the central problem of pigeon navigation remains unsolved; the sensory basis of orientation in both type II and type III homing is still a matter for speculation. The results achieved to date point towards a sort of celestial navigation based upon the sun and sky brightness patterns.

VARIATION OF HUMIDITY WITH HEIGHT IN THE LOWER ATMOSPHERE

DURING the Second World War, a need arose for detailed information on the variation of humidity with height in the lower layers of the atmosphere in connexion with research into the refraction of the electromagnetic waves used in radar and high-frequency radio communication. The temperature structure in the vertical and its variations were known in considerable detail from work at Porton and Leafield, by Sir Nelson Johnson and Mr. G. S. P. Heywood, published in Geophysical Memoirs 46 and 77, but no such information existed for humidity. To remedy the deficiency the Meteorological Office set up apparatus near Rye, Sussex, recording temperature and humidity at 1·1 m. and on an open-lattice mast at heights of 15·2, 47·2 and 106·7 m. Temperature was recorded continuously by resistance thermometers and relative humidity by Gregory humidiometers enclosed in aspirated screens.

Geophysical Memoir 89[*] describes the apparatus in detail and summarizes and discusses the observations made at Rye during July 1945–June 1948. The temperature observations at Rye differed little in their main properties from those made by Johnson and Heywood, and in this note attention will be concentrated on the humidity. Humidity is expressed in the Memoir in milligrams of water vapour per cubic metre; mean values of this quantity at 1·1 m. are about 11,000 in midsummer and 5,000 in midwinter.

The variation of humidity with height is similar to the variation of temperature with height. There is generally a decrease (lapse) with height in the middle of the day and an increase (inversion) at night. The largest variations occur near the ground. The vertical gradient decreases with height.

The diurnal variations are of great interest, especially on clear days in summer when, as would be expected, they are most pronounced. Humidity near the ground on clear days increases quickly after sunrise as insolation evaporates water from the ground surface, and there is a sharp maximum two to three hours later. A lapse of humidity forms and quickly becomes of the order of 1,000–1,500 mgm./m.^{3} between 1·1 m. and 106·7 m. Increasing turbulence then transports water vapour upward more quickly than it is evaporated so that humidity near the ground and the lapse-rate decrease again. In the evening turbulence decreases, so humidity near the ground increases again, until after sunset the lapse of humidity changes over to an inversion and water vapour diffuses down to condense on the ground. There is a minimum of humidity and the most pronounced inversion at dawn; an increase of some 800 mgm./m.^{3} between 1·1 m. and 106·7 m. is then observed. After sunrise the inversion breaks down very quickly as evaporation begins.

The Memoir concludes with a description of the temperature and humidity gradients observed in radiation fog. The general picture is of an inversion of both temperature and humidity in the lowest layers in the early stages of fog. These inversions weaken in low layers as the air cools further and the depth of fog increases but extend upwards to continually increasing heights. Relative humidity inside the fog remains almost constant but need by no means reach 100 per cent.

The Memoir reports an investigation of fundamental importance in meteorology and will undoubtedly be consulted as much as its similar predecessors, Nos. 46 and 77.

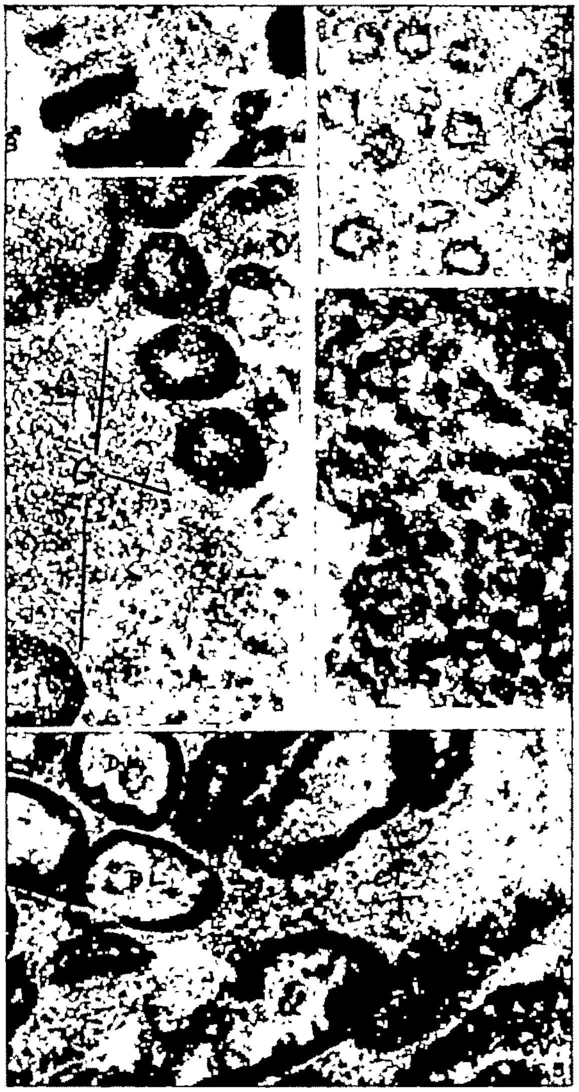
HISTOCHEMISTRY OF XANTHINE OXIDASE

By DR. GEOFFREY H. BOURNE

Histology Department, London Hospital Medical College

IT was shown by Shelton and Schneider[1] that a mixture composed of purified xanthine oxidase, hypoxanthine and phosphate buffer at a *p*H of 7·5, when incubated with neotetrazolium, reduced the latter to an insoluble coloured diformazan. The reaction was similar to that produced by succinic dehydrogenase in the presence of succinate. Since the latter enzyme has been demonstrated histochemically by this method (Seligman and Rutenberg[2]), it was decided to attempt the histochemical localization of xanthine oxidase in a similar way.

A substrate mixture containing 3×10^{-4} *M* xanthine in 0·075 *M* sodium pyrophosphate buffer, giving a *p*H of about 8·2, was used and to this was added 50 mgm. of neotetrazolium chloride. Nitrogen was bubbled through this mixture for 20 min., and it



(1) Xanthine oxidase reaction in jejunal epithelial cells. Note negative nucleus (*N*) and negative brush border and distal portion of cell (*B*). × 360

(2) Portion of inner part of cortex of kidney to show positive xanthine oxidase reaction in descending limbs of Henle's loops. Negative nuclei (*N*) may be seen. × 195

(3) Glomerulus (*G*) containing some xanthine oxidase-positive granules, surrounded by proximal convoluted tubules containing many positive granules. Negative reaction by the nuclei is particularly obvious in one of the tubes (*A*). × 330

(4) Granular xanthine oxidase reaction in the liver cells. Nuclei are negative but this is obscured by the large number of granules in the cytoplasm. × 240

(5) Inner part of cortex of kidney. Note positive xanthine oxidase reaction by descending limbs of loops of Henle (*DL*) and by convoluted tubules (*CV*). Negative reaction by nuclei in both types of tubule is apparent. Collecting tubules (*CT*) only slightly positive. × 600

was divided between two glass-stoppered tubes each of which was filled to the top so that when the stopper was replaced all air was excluded. In one of these tubes sections, 50 μ thick, of fresh frozen tissue were placed; in another, slices of tissue about 2 mm. thick. (Best results were given by the latter.) The tissues used were liver, kidney, spleen and small intestine, these having been shown by Westerfeld and Richert[3] to have the highest xanthine oxidase activity. When whole pieces of intestine were used, they were opened up so that the epithelial cells were in direct contact with the substrate.

The reduction of the tetrazolium began even in the cold, and in a few minutes the tissues had a pale pink colour due to the formation of diformazan. Incubation was carried out for 1 hr. Following this, the sections and the pieces of tissue were washed in distilled water and placed in 10 per cent formaldehyde for 3 hr. The frozen sections were then washed and mounted in Apathy's medium. The pieces of tissue were washed and embedded in 'Carbowax' and sections 8 μ thick were cut and, after removal of wax, mounted in glycerine jelly.

Two types of reaction were observed in the cells. First, a dark red diffuse reaction (which according to Seligman and Rutenberg[2] is given in the succinic dehydrogenase reaction by regions of low activity) and a deep blue granular reaction which, according to the same authors, is given by regions of high activity. All cells which gave a positive reaction showed it in this dual form. The granular reaction appeared to be in formed elements of the cell which appeared similar in form to mitochondria. It is possible that the low activity in other parts of the cytoplasm may have been due to diffusion of the enzyme during incubation from these sites of high activity. It was noteworthy, however, that the nucleus in all cells appeared to be completely negative, and to be not even a region of low enzyme activity; thus the xanthine oxidase reaction is entirely cytoplasmic in distribution. One cannot, of course, be certain that the nucleus is devoid of activity even so, since the nuclear membrane may be impervious to the passage of the substrate and/or the tetrazolium; nevertheless, this negative reaction is striking. Another negative area is shown by the brush borders of the epithelial cells of the small intestine. Not only is the brush border entirely devoid of any reaction, but a small band of cytoplasm immediately beneath it is also negative. The greatest reaction seems to be between this region and the nucleus, although the basal part of the cell is also very active. It is significant that there should be completely negative portions of the cytoplasm which are indeed sharply delineated from the positive areas. This fact suggests that the non-granular low-activity reaction is not due to diffusion from centres of high activity.

A granular reaction was also given by the bases of the crypts of Lieberkuhn. The smooth muscle gave a slight reaction (granular), and the connective tissue between the muscle layers was more active than the muscle.

In the spleen certain cells in the red pulp, the identity of which could not be established, gave a greater reaction than any other parts of the organ.

In the liver the peripheral cells of the lobules appeared more active than the more centrally placed cells, a fact which is in keeping with other evidence (see, for example, Malaty and Bourne[4]) that the outer cells are metabolically more active. The granular reaction in the liver cells is not as uniform as it is in the cells of other tissues. There seem in addition to the round granules to be many short and elongated rod-shaped positive objects, and it is difficult to be certain that these represent formed elements of the cells. Some of them look more like crystals of diformazan. However, if they are the latter, it is curious that they should be present only in liver and not in other tissues incubated with them in the same substrate in the same tube.

In the kidney the reaction is similar to that for succinic dehydrogenase in being most intense in the proximal convoluted tubules and the descending limbs of Henle's loops. In the latter it is more diffuse than granular. The glomeruli are largely negative, though there are a few positive granules in the cells. The ascending limbs of Henle's loops and the distal convoluted tubules also give a reaction. The collecting tubules give a mixed reaction and some of them appear positive even in the medullary part of the kidney.

It is desirable that further work be carried out on this reaction before proper assessment of the significance of the results can be made; but the two facts of great interest which have emerged from it are the negative reactions given by the nuclei of all the tissues examined and by the brush borders.

I am greatly indebted to Prof. F. Bergel and Mr. R. C. Bray, of the Chester Beatty Research Institute, for a supply of buffered substrate and for helpful suggestions; to Dr. H. A. Malaty for cutting some of the frozen sections; and to Mr. J. Linder for cutting 'Carbowax' sections of some of the preparations. The neotetrazolium used was in part a gift from Dr. W. C. Schneider, of the National Institutes of Health, Bethesda, U.S.A., and in part purchased with the aid of a grant from the Medical Research Funds Committee of the London Hospital.

HUMAN VISUAL PURPLE

By Dr. F. CRESCITELLI* and Dr. H. J. A. DARTNALL

Medical Research Council Group for Research in the Physiology of Vision, Institute of Ophthalmology, London

BIOCHEMICAL studies of the visual pigments have been restricted almost entirely to animals lower than man. The frog's retina has proved a convenient source of material and much precise information exists on frog visual purple. In contrast, knowledge of the corresponding human pigment is meagre although a wealth of data on human vision has been collected. This situation has led to the use of the frog data in the interpretation of certain human visual functions. The assumption that the scotopic pigments of the two organisms are identical is based on the resemblance between the absorption spectrum of frog visual purple and the human scotopic sensitivity curve.

Recently, through the co-operation of the surgeons and staff of the Moorfields, Westminster and Central Eye Hospital (Moorfields Branch), we have obtained some human material for examination. The purpose of this article is to present evidence that human visual purple is spectrophotometrically different from frog visual purple and to apply the new data to some old problems.

The present information was obtained from a dark-adapted eye removed because of the presence of a ciliary body melanoma. The patient, a man aged fifty-three, readily consented to wear a light-proof mask over both eyes for three hours. The operation (removal of right eye) was then carried out in deep red light in an otherwise completely dark operating theatre. The eye was placed in Ringer–Locke's solution in a lightproof container and brought to the laboratory. Here, again in deep red light, the retina was obtained by the following procedure. After first removing the cornea and lens which were required for other purposes, the eye was divided into two portions by cutting around at the level of the ora serrata. The anterior portion containing the melanoma was then passed to the Department of Pathology for routine examination. The posterior portion was gently squeezed to extrude the vitreous. With a soft paint-brush the retina was then eased away from the underlying choroid. The retinal mass was picked up with forceps and, after severing its connexion with the optic nerve, was placed in 35 per cent sucrose solution.

Vigorous shaking then caused the outer limbs of the retinal end organs to break off[1] and become suspended in the sucrose solution[2]. On centrifuging, the retinal debris was precipitated; but the outer limbs remained suspended in the supernatant. This was pipetted off. A second suspension of outer limbs was obtained by adding further sucrose solution to the residue and repeating the whole procedure. The two suspensions were diluted to reduce the specific gravity, and on centrifuging them the outer limbs were precipitated. These were washed and bulked and then treated with two successive 0·5-ml. portions of freshly prepared 2 per cent digitonin solution to extract the visual pigment. The combined extracts were made alkaline by the addition of 0·1 ml. of saturated sodium borate solution.

Portions of this solution were examined spectrophotometrically using apparatus and technique previously described[3]. The absorption spectra before and after exposure to white light are shown in Fig. 1*A* by the curves marked 'unbleached' and 'bleached', respectively. In general form these curves are typical of results obtained with extracts from the retinæ of other vertebrates. Both before and after exposure to light the solution was thermally stable, as is shown by the correspondence between the measurements made going up the wave-length scale (open circles) with those going down (filled circles). No subsequent regeneration was observed; even after 17 hr. in darkness at 20° C., the absorption spectrum of the bleached solution remained unchanged.

The extract was, of course, a crude preparation containing impurities. Consequently the 'unbleached' curve of Fig. 1*A* is only a rough approximation to the true absorption spectrum of the visual pigment. The left-hand limb of the curve is most affected since the impurities absorb with increasing strength as the short wave-length extreme of the visible spectrum is approached.

For analytical purposes it is often useful to plot the change in density at each wave-length which occurs on bleaching. Such difference spectra eliminate the effects of stable impurities and express simply the difference in spectral properties between the photosensitive pigments and their photoproducts. Provided the *p*H is controlled (necessary because the absorption spectra of the photoproducts are dependent on *p*H), difference spectra are accurately reproducible and afford a means of comparing results from different species with a high degree of precision[4].

The difference spectrum derived from the 'unbleached' and 'bleached' curves of Fig. 1*A* is plotted as open circles in Fig. 1*B*. This figure also includes

---

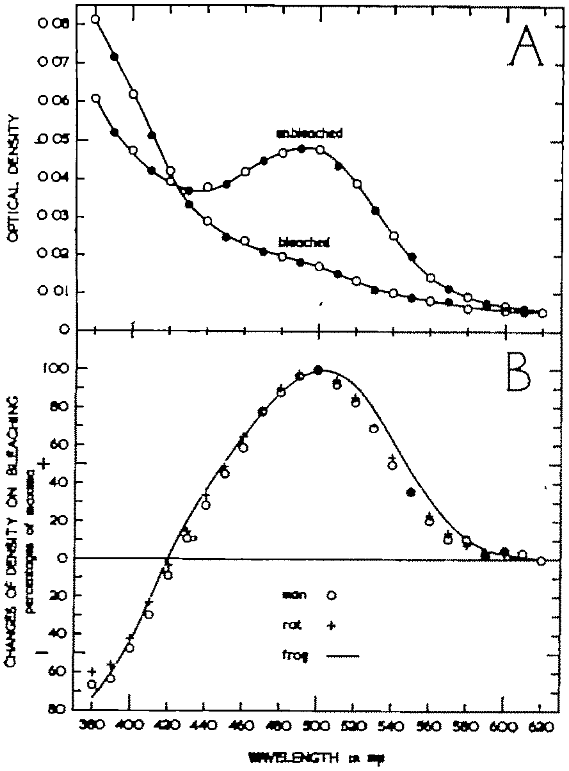

Fig. 1. *A*, absorption spectra of the human extract before and after exposure to white light. ○, readings taken from 380 to 620 mμ; ●, return readings from 610 to 390 mμ. *B*, comparison of the difference spectra (max. = 100) for man (pH = 8·2), albino rat (pH = 8·5) and frog, *Rana esculenta* (pH = 8·6). All measurements at 20° C.

results previously obtained in this laboratory for the albino rat (crosses) and the frog (continuous line). The difference spectra for man and rat agree with one another but differ systematically from that for the frog, which has a maximum at a wave-length some 5–6 mμ higher. Since the absorption maximum of frog visual purple is at 502–503 mμ, this indicates the position of the maximum for the human (and rat) pigment to be at 497 mμ within limits of ± 2 mμ. This substance, in accordance with the nomenclature system proposed by one of us[3], may be called visual pigment 497.

The true absorption spectrum of this pigment will not be directly known until pure solutions of it can be prepared. In the meantime, however, the probable curve can be constructed from the visual pigment nomogram[4], a device which depends on the observation that all the broad-band visual pigments known have absorption spectra of similar shape when plotted on a frequency scale. The curve so obtained for visual pigment 497 is shown in Fig. 2 by the continuous line, together with the absorption spectrum of visual pigment 502 (frog visual purple) by the interrupted line.

To ascertain the role of visual pigment 497 in human vision, it is necessary to relate its absorption spectrum to a retinal sensitivity curve. The presence of this pigment in the rat retina, which is almost devoid of cones, suggests it to be a rod pigment and hence relevant to a scotopic function.

Many measurements of the human scotopic sensitivity have been made; the latest and, probably, the best being by Crawford[5], who reviews the earlier work. Crawford's relative sensitivity values (mean of fifty observers) were specified with respect to the energy incident on the cornea. They are shown in Fig. 2 by the symbol ● after re-calculation to refer to the quantum intensities incident on the visual pigment layer of the retina; in the transformation, Ludvigh and McCarthy's values[6] for absorption of light by the pre-retinal media were used. In Fig. 2 the retinal sensitivities are compared with the absorption spectra of visual pigment 497 (man) and visual pigment 502 (frog). Apart from the violet region of the spectrum where variations in individual observers make the allowance for pre-retinal absorption uncertain, the sensitivity data are in excellent agreement with the constructed curve for visual pigment 497 and in distinctly worse agreement with the curve for visual pigment 502. This strongly suggests that visual pigment 497 is the scotopic pigment of human vision and supports the contention of a species difference between the pigments of frog and man.

On theoretical grounds a further factor should be considered when relating a pigment with a visual function. Sensitivity data should be compared with the amounts of light absorbed by the pigment *in situ*[7]. In the present instance the concentration of visual pigment 497 was calculated to be equivalent to an optical density of 0·016 (at 497 mμ) assuming an even distribution over a retinal area of 9 cm.^{2}. This figure, in good agreement with the value 0·018 derived[7] from König's results, includes amounts of the pigment found in the retinal washings and in a final extract of the rod-denuded retina as well as in the main extract. An optical density of 0·016 corresponds to an absorption of only 3·5 per cent. For such a small concentration the curve expressing the spectral variation of light absorbed is scarcely distinguishable from the absorption spectrum and there is little point with the present data in refining the comparison.

In another respect, however, this result, if accepted as normal, has a greater practical significance. Hecht, Shlaer and Pirenne[8] found that, for light of wavelength 510 mμ, between 54 and 148 quanta incident on the cornea were sufficient to stimulate vision under

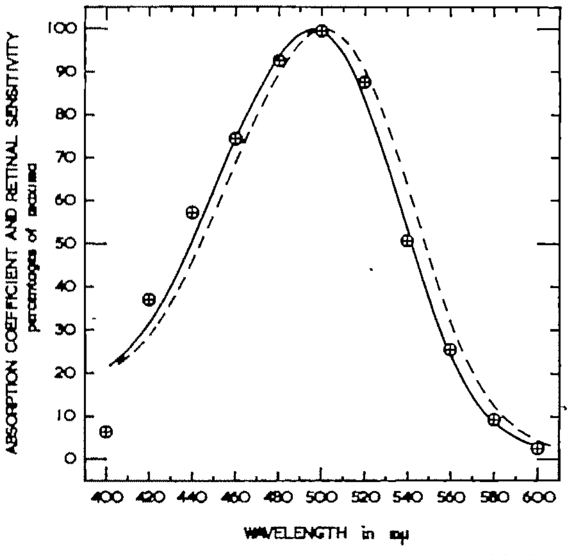

Fig. 2. Comparison of the human retinal scotopic sensitivities (●) with the absorption spectra of visual pigment 497 from man (———) and visual pigment 502 from the frog (– – –)

optimal physiological conditions. Allowing 4 per cent loss by reflexion at the cornea, 50 per cent loss by absorption in the pre-retinal media and 20 per cent absorption of the remaining light by the visual pigment, they arrived at 5–14 quanta as the retinal stimulus threshold. Their figure of 20 per cent absorption by the visual pigment was based on an indirect calculation in which it was implied that the scotopic pigments of frog and man were identical. If, in place of this figure, the present one of 3·5 per cent is used, the stimulus threshold becomes 1–3 quanta approximately. This result, if confirmed, may have a considerable bearing on theories of excitation of the retinal rods. [March 16.

A WIDESPREAD FUNGISTASIS IN SOILS

By Dr. C. G. DOBBS and W. H. HINSON
University College of North Wales, Bangor

RESEARCH in soil mycology at Bangor has been carried on since 1947. Starting with an attempt to discover where, and to what extent, the common mucorine moulds grow and sporulate[1] in relatively undisturbed forest soils, it was soon extended to include other 'sugar fungi'—to use Burges's[2] term for soil fungi unable to attack cellulose or lignin.

Preliminary work, in part by G. D. Holmes (unpublished) in 1948, showed that cellulose film, buried in the soil without protection, is not a satisfactory substrate for studying the growth of such moulds, although when protected between glass slides it supports their growth and some sporing.

From October 1950 the work has been carried on by W. H. Hinson. The use of nutrient in the soil was entirely abandoned, and a variant of the Rossi–Cholodny slide method, suggested by the 'slide-traps' of La Touche[3], was adopted. This consisted of two sterile microscope slides, held together by rubber bands, the slides in contact at one end, but separated by a glass fibre 0·7 mm. thick at the other. These 'gap-traps' were inserted in the faces of soil pits in two forest soils, under spruce and beech respectively, and lifted after fourteen days, at which time numerous mycelia may normally be seen spreading from the edge on the two protected glass surfaces, whereas on the surfaces exposed to the soil hyphæ were seen only sporadically at points where the soil was judged not to have been in contact.

Isolations from these 'gap-traps' gave a range of 'sugar fungi', mainly *Penicillium* spp. and Mucorales, which showed variations of only minor importance with weather, season, soil horizon or site, and in the course of the work it became clear that spores, germinating in condensed water between the slides, provided the origin of many, at least, of the hyphæ seen and the isolations made. Chesters[4] has pointed out the importance of condensation on buried slides in changing the soil environment; but the significance of spore germination in such condensed water in a protected niche within the soil mass does not seem to have been fully realized hitherto. It raises the question: Why have not such spores germinated previously in the soil itself, where water is amply available?

The behaviour of spores in the soil is difficult to observe, though Legge[5], by an ingenious technique using glass-fibre tape, has recovered the relatively large oospores of *Phytophthora* spp., some ungerminated, after as long as a year. We found that spores of *Penicillium frequentans*, placed in a sintered glass pad in contact with soil, after a week showed negligible germination restricted to a few lodged on upper surfaces of the glass on which condensation may have occurred. Spores of *Penicillium nigricans*, chosen for its recognizably spiny conidium, when placed directly in moist soil, could be recovered from the centre of the soil mass, ungerminated, up to one month. Later it was found possible to demonstrate 100 per cent inhibition of germination, by the use of cellulose film in the soil, which was impossible to demonstrate by these preliminary methods; but they at least showed that the inhibition is present in the soil itself and is not generated in some way by the film.

The cellulose film used is the thinnest commercial wrapping material, about 20 μ thick, which is cut into 2-in. squares, boiled to remove the surface dressing, lightly autoclaved, and while still slightly damp, dusted with the test spores, if xerospores, or sprayed with a dense suspension of them and allowed almost to dry in the case of gloiospores. The square is then folded with the spores inside, partially buried in moist soil, and pressed firmly so as to secure intimate contact with the soil surface. With every fresh soil so far tested in this way the germination of the test spores has been completely inhibited on the area of the film with which the soil is closely in contact, and on no other part of it. Germination and growth occur freely on the 'margins', that is, the parts of the film not in contact with the soil, but the hyphæ will not grow into the soil-contact area. No such complete suppression of germination occurs on parts of the film pressed between soaked filter papers, or certain minerals of similar wetness, or autoclaved soil, which last, in fact, stimulates germination as compared with the 'margins'. When the 'folds' from living and autoclaved soils are exchanged after a few days, germination proceeds on the first, and hyphal growth is checked on the second.

Kaolin, alumina and slate dust have been found to reduce, but never to extinguish, germination in the 'folds', as compared with soaked filter paper, sand and silica, which allow of normal germination; but this reduction is absent when the film is not folded, being merely pressed down firmly on the moist soil. Under these conditions, the inhibition is fully shown with normal soils, provided that precautions are taken to secure good contact and to prevent condensation on the exposed test surface. Similarly placed agar films have so far given inconclusive results, for though some inhibition is exhibited, its interpretation is complicated by the growth of hyphæ from the soil into the agar. The inhibition has been demonstrated with a somewhat thicker cellulose film (about 40 μ), but was apparently not present when the thickest film obtainable (about 120 μ) was used. It has also been demonstrated in the natural soil out of doors; but most of the tests have been carried out in glass dishes in the laboratory, the 'margins' being used as controls.

The normal test period is four days at room temperature though some 'folds' have been kept in the soil for as long as five weeks without germination of the spores; but more often results are obscured after a few weeks by bacterial, insect or mite attack on the film, especially if the inside of the 'fold' is contaminated with soil. If the sweet dressing commonly present on commercial cellulose film is not completely removed by boiling in water, a breakdown of the inhibition, accompanied by bacterial growth, may occur within a few days.

A strain of *Penicillium frequentans* Westling isolated from forest soil and having a high percentage germination in water was chosen as the main test organism. Up to the present the test outlined above has been applied to soils from fifteen sites in North Wales and one in Warwickshire, as well as subsoils from several sites.

Complete inhibition was found in every sample of fresh soil tested. These soils may be summarized as follows: *Forest soils*, 5; under Norway spruce, beech, sycamore (2) and oak. The first two have been tested at every level down to mineral soil at 1 ft. The half-rotted litter both of spruce and beech possesses the inhibiting effect. *Grassland soils*, 5; waste ground, rough grazing over acid igneous rock, a moderately good grass ley, drift material at 1 ft. under mown turf, and a calcareous turf over carboniferous limestone (Anglesey). This last was tested down to broken limestone at 6 in. *Cultivated garden soils*, 3; poor, average, heavily composted (from Warwickshire); also John Innes potting compost. *Waterlogged soils*, 3; fresh mud from a spring, black decaying pool-bottom material, calcareous peat brought up from levels down to 3 ft. under standing water (Llyn Cadarn, Anglesey). *Two subsoils* also showed complete inhibition: a stiff clay from 3 ft. depth near a garden compost heap, and the finer fractions of a gritty subsoil at 2–2½ ft. depth from a building excavation on a formerly wooded site.

Incomplete inhibition, allowing germination of a minute, fractional percentage of spores compared to controls, was found in three subsoils: drift material at 2 ft. and 3 ft., stony subsoil augered from 3½ ft. under rough pasture over acid, igneous rock, a similar material from 3 ft. to 4 ft. depth from a drain excavation under a wide path.

Germination, not less than that shown with kaolin, has been found, so far, in drift material at 6-ft. depth, and in four samples of gritty subsoil from depths of 3 ft. to 20 ft., sent by Mr. J. Goodwin from an open-cast coal mine near Aberdare, Glam.

The four samples described as 'drift material', which was a silty, mottled clay showing signs of impedance, form a series in depth taken from one pit. The samples were almost indistinguishable in appearance, except that the uppermost, at 1 ft., showed traces of fine roots. This showed complete inhibition. With the 2-ft. sample, an occasional germ tube could be found, after a search. At 3 ft. there were a few more, but still too few to estimate as a percentage. At the 6-ft. level about 5 per cent of the spores germinated. The 1-ft. sample, after autoclaving, stimulated germination, whereas autoclaving made no change in the test results given by the 6-ft. sample.

The inhibition was not shown by three old dried soils, kept in bottles for periods up to twenty years. These, when moistened, became mouldy in a manner resembling autoclaved soils. The effect was present in a clod of forest soil which had been air-drying at room temperature for six weeks, but had disappeared by the seventh week, though it was then still present in another clod which lay beside it. Stored, powdered slate dust gave a rather poor germination which was not improved by autoclaving the material.

The following results have been obtained with the forest soils originally investigated, and with *P. frequentans* as test fungus:

The inhibitory effect is not removed by repeated leaching with distilled water, nor by percolating for seven days. In neither case does the water acquire the effect. It appears to be present to some extent in pressed-out soil water, but preliminary results are inconclusive, and even more so for Seitz-filtered sterile extract. The effect disappears completely from soil shaken up for five minutes and washed through a funnel with citrate–phosphate buffer solutions at *p*H values of 4–7·5, but remains after similar treatment with a phosphate buffer series from *p*H 4·5 to 8, and even after hydrochloric acid at *p*H 1, the soil being returned to *p*H 5–6 by washing before test. The citrate-treated samples afterwards grew moulds. The effect is lacking from the filtrates in every case.

When the soil is moistened with dilute solutions of glucose plus inorganic salts germination takes place, though it is less than on the control margins. This occurs even with a trace of glucose, as little as 0·1 per cent; but if a fresh test 'fold' is inserted after three days, the inhibition is found to have returned, though not completely in the case of the strongest solution used (4·4 per cent) with which a few spores germinated. A similar series set up with asparagin (plus salts) solutions from 0·1 to 2 per cent showed no germination except with the 2 per cent asparagin which gave a very few germ tubes.

Moist, sieved soil, tubed and immersed in a water bath for one hour at 40°, 50° and 60° C., showed full inhibition after 40° C., stimulated germination after 60° C., and an intermediate result with about 50 per cent of the control germination after 50° C. Soil exposed to ether vapour for twenty-four hours gave stimulated germination; but the inhibition restored itself after three days. Wetting with acetone also removed the inhibition, but a prolonged washing in a shaker with distilled water for 13½ hours restored it. Plating out showed that neither of these treatments had completely sterilized the soil. An intimate mixture of 10 per cent by weight of finely divided charcoal with soil completely removed the inhibition, and the mixture afterwards grew moulds on the surface. The inhibitory effect is not restored in a short time by re-inoculation of autoclaved soil with fresh soil, nor by exposure of dried soils to atmospheric infection. A re-inoculated sample of autoclaved garden soil still lacked the effect after two months, and of forest soil after four weeks. The test species usually spores freely on the surface of these soils; but germination remains uninhibited during this growth and after it has died down. A test over potash showed that carbon dioxide is evolved more rapidly by autoclaved soil during this phase of mould growth than by a control of unautoclaved soil possessing the inhibitory effect.

Up to the present the fungi tested have been, with a few exceptions, those isolated from the original forest soils. A random mixture of spores from the colonies on a soil plate was completely inhibited by the soil from which they were cultured. The following species have been tested separately and found to be inhibited: *Penicillium frequentans* Westling, *P. expansum* Link, *P. nigricans* (Bainier) Thom, *P.*

communs Thom, *P. waksmani* Zaleski, and ten other species not all fully identified, including some from each division of the genus; *Cladosporium herbarum* Link ex Fr., *Trichoderma viride* Pers. ex Fr., *Macrosporium* sp., *Chaetomium globosum* Kunze (ascospores), *Mucor hiemalis* Wehmer, *Mucor plumbeus* Bonorden, *Mortierella ramanniana* (Möller) Linnemann, *Mortierella baineri* Costantin, *Rhizopus nigricans* Ehrenberg.

Most of these are 'sugar fungi'; but *Chaetomium globosum* attacks cellulose. So far no fungus tested has been able to germinate or grow on the soil-contact area; but that such fungi exist seems probable from casual observations. With one soil (composted garden loam from Warwickshire) a dense growth of sterile mycelium was found on the outside of the 'fold', and various sterile mycelia, some of them bearing clamp connexions, have been seen in some of the soils used; but the test method has not yet been satisfactorily adapted to such mycelia, nor to spores which require nutrient or other special conditions for germination.

The evidence here presented is insufficient to identify the factor causing the inhibition; but it does seem to differentiate it from most of the antibiotics produced by micro-organisms, the production of which is usually stimulated by the presence of carbohydrates. In the case of patulin, one of the antibiotics shown to be produced in soil, Grossbard[6] found that, even in sterilized soil, the addition of carbohydrates was necessary for its manufacture by *Penicillium patulum*. Gregory, Allen, Riker and Petersen[7] have demonstrated antibiotic activity in unsterile soil supplemented with organic matter, and Wright[8] has shown that gliotoxin can be produced by *Trichoderma* in unsterilized Wareham Heath soil, but only with addition of dried clover. Jefferys[9] has shown that inactivation of gliotoxin is more rapid in neutral garden loam than in the acid Wareham Heath soil and that a number of antibiotics have a limited range of stability as regards *p*H. Hessayon[10] has shown that trichothecin can be produced in unsupplemented, sterilized soil; but this antibiotic is remarkably thermostable, and possesses other distinctive features.

Since this article has gone to press, Hessayon[11] has reported that spores of *Trichothecium roseum* fail to germinate in unsterilized soils, although growth of a mycelial inoculum takes place; and also that a factor inhibitory to the growth of *T. roseum* is present in the ether extract of unsterilized soils.

The indications of the work at Bangor are that there exists in the soil a widespread fungistatic factor, which, from its distribution in depth, possibly coexists with some organic constituent of the soil. It seems to be masked, rather than destroyed, by the presence of glucose even as a trace, or of nutrients liberated from micro-organisms killed by heat or toxins, since it returns, presumably when the nutrient has been absorbed by other micro-organisms in the soil; but it may be removed by severe heating or prolonged desiccation, as it is then not rapidly restored. The only comparable phenomenon hitherto described appears to be that found in Wareham Heath soil by Rayner and Neilson-Jones[12]; but that effect, usually regarded as toxic, is so strong that it inhibits the growth of moulds on the surface of nutrient agar containing citric–phosphate buffer, and may even be lethal to mycelium. Nevertheless, it has great similarity to the effect described here in its apparent instability apart from the soil, and its behaviour after partial sterilization of the soil. The finding by Neilson-Jones of some fungitoxicity in the more normal Oxshott Heath soil is also significant. It is premature to speculate on the relationship between these two phenomena; but they must surely fall into the same general class. Despite the intensive work of Brian[13] and his colleagues, mainly on the antibiotics produced by organisms isolated from Wareham Heath soil, that phenomenon has not yet been traced to its source, and it will not therefore be surprising if this more widespread, but subtler, effect fails to yield up its causal factors, biological or biochemical, soon or easily. For this reason it seems advisable to publish these results at this preliminary stage, especially as the phenomenon may well prove to be generally present in soils and to fill a significant gap in the puzzle-picture which confronts the soil mycologist.

That spores must lie dormant in soil is an inescapable deduction from the fact that they germinate in large numbers whenever soil is placed in contact with nutrient media; but that the nutrient is not necessarily responsible for their germination is clear from the fact that many spores germinate in distilled water. In recent years it has been widely realized, as pointed out by Garrett[14], that soil dilution plates of the classical type designed by Waksman[15] greatly favour the heavily sporing 'sugar fungi', and techniques, such as those of Chesters's[16] immersion tubes and Warcup's[17] soil plates, have been devised to minimize this effect. There can be no doubt that these methods isolate mycelia where such are present; but unless any given isolate can be shown to be able to grow in the habitat from which it was obtained, there is no likelihood that it was present there in active mycelial form. With regard to those common isolates which can be shown to be subject to inhibition of germination in the soil, it is doubtful whether we are entitled to refer to them as members of the soil flora. Perhaps it might be better to borrow the term which P. H. Gregory applies to air-borne spores, and to refer to them as the soil 'spora'. So far as these fungi are concerned, if they grow in the soil at all, as many of them almost certainly do, it must be in special habitats forming 'islands' in the sea of inhibition. So far as present indications go, such habitats may be formed by some, though not all, organic materials, including nutrients liberated from soil organisms dying or killed by various means such as, for example, long drying or insolation at the surface. Such habitats may provide sufficient nutrient for sporulation. It is possible also that occasionally germination and limited growth may occur in freshly brought up subsoil and in condensed or rain water which has not mixed with the soil; but in the absence of nutrient such germlings would generally die without sporing. Susceptibility to the inhibition is likely to have a high survival value for fungi with spores which germinate in water without nutrient.

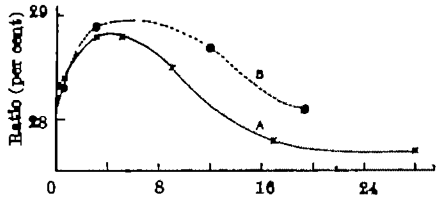
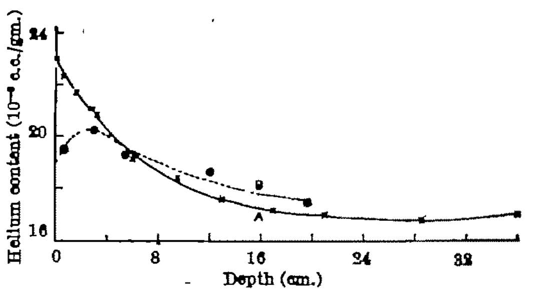
Production by Cosmic Rays of Helium-3 in Meteorites

THE helium content of iron meteorites varies from less than 10^{-8} c.c. to 4×10^{-5} c.c. per gm. [1]. Since their uranium and thorium content is fairly constant, this variation was considered as an indication of their very different ages. During the past decade, however, it has been discovered that by the impact of cosmic rays on matter helium is formed, and Bauer[2] and Huntley[3] have pointed out that a considerable part of the meteoritic helium might have this origin. Although attempts to calculate this amount on the basis of our published figures and of certain assumptions about the masses of meteorites[4] were open to criticism[5], it was predicted[6,7] from cosmic ray observations that in meteoritic helium the proportion of helium-3 to helium-4 may amount to about 30 per cent, and in five iron meteorites helium-3/helium-4 ratios varying from 17·8 to 31·5 per cent were found[8].

These results were considered as proving the cosmic ray origin, in the meteorites richest in helium, of the helium-3 and most of the helium-4; but various questions concerning the mechanism of the helium formation by cosmic rays and the relative amounts of the two helium isotopes thus created remained undecided[9]. It seemed promising to study the dependence of the helium content of meteorite samples on their distance from the surface. Owing to the attenuation of cosmic rays inside the meteorite, a 'depth effect' ought to exist, if the helium was formed by these rays. Several attempts to discover such an effect were unsuccessful[9,10], and it became clear to us that one could hope to detect it only in samples from the interior of a very big rounded iron meteorite with accurately measurable helium content. The 1,200-lb. mass of the Carbo meteorite[11] in the Museum of the Mineralogical Department of Harvard University looked promising, and the curator, Dr. C. Frondel, kindly agreed to have samples collected from various depths by two bore-holes extending right to the centre.



Helium-3/helium-4 ratio: (*A*) longitudinal hole; (*B*) transverse hole



Total helium content: (*A*) longitudinal hole; (*B*) transverse hole

The extraction of helium from the Carbo drillings and its purification and measurement were carried out by the methods described elsewhere[12]. To facilitate handling in the mass spectrometer, each helium sample of 10^{-4} c.c. (N.T.P.) was diluted with about 10^{-3} c.c. (N.T.P.) of argon and sealed in a glass tube with a break seal. To introduce the gas into the spectrometer the seal was broken, and the gas compressed into the sample reservoir to obtain a convenient ion-beam strength. Standard samples of helium-3/helium-4 mixture were run at the commencement and end of each working period.

The results of our measurements can be seen from the accompanying table and graph. The precision of the manometric helium values is about ± 0·1 per cent, of the mass-spectrometer values better than ± 1 per cent of the helium-3/helium-4 ratio. It is not yet possible to give a full explanation of the details of the curves; but the main results are as follow.

Depth (cm.)	Helium content ($\times 10^{-6}$ c.c./gm.)	$\frac{\text{Helium-3}}{\text{Helium-4}}$ (per cent)
	Longitudinal hole	
0	23·03	—
0·5	22·30	28·4
1·5	21·70	—
2·5–3	21·06	28·8
3	20·81	—
6	19·05	28·8
9·5	18·53	28·5
13	17·60	—
17	17·24	27·8
21	17·04	—
28·5	16·83	27·7
36	17·13	—
	Transverse hole	
0·5	19·45	28·3
3	20·25	28·9
5·5	19·24	—
6	19·01	—
12	18·64	28·7
19·5	17·50	28·1

Both the total quantity of helium and the percentage of helium-3 change regularly with depth and are smallest in the interior. The highest values for the helium-3/helium-4 ratio are found a few centimetres below the present surface of the meteorite; this is most probably a consequence of the lower energy α-particle component of the primary cosmic radiation being brought to rest within a few centimetres of the surface[7]. In one of the bore holes also the total quantity of helium increases slightly over the first few centimetres and then decreases towards the centre; for this effect irregularities in the shape of the meteorite present during the period of its cosmic irradiation may be responsible, or, alternatively, it may reflect the eccentric position of the present mass inside the original one. We hope to be able to say more about the original form of the meteorite after analysing samples from a third bore hole drilled right through the meteorite which Dr. Frondel has kindly agreed to provide. We think it less likely that a diminution of the uranium or thorium content of the meteorite near this part of the surface is the cause of the helium decrease; we did not find any marked variation of the uranium content. (In a sample from the surface, $0·52 \times 10^{-8} \pm 0·02 \times 10^{-8}$ gm. per gm.; from the interior, $0·56 \times 10^{-8} \pm 0·04 \times 10^{-8}$ gm. per gm. The material at our disposal was not sufficient to determine the thorium in the drilled samples; near the surface we found $0·63 \times 10^{-8} \pm 0·42 \times 10^{-8}$ gm. per gm. [12].)

It is not yet possible to say how much of the helium-4 in the Carbo meteorite is of radiogenic origin, since the quantity of helium-4 produced by cosmic rays together with helium-3 is not accurately known[6,7] and depends on the relative proportions of the primary and secondary radiations. From observations on another meteorite, we concluded[8] that there the helium-4 of cosmic ray origin could not be more than 3·2 times the helium-3; the limit derived for the Carbo meteorite is 3·5. The possibility of determining the quantity of radiogenic helium on which to base an age calculation is obviously much greater in meteorites with a low helium-3/helium-4 ratio[8,9].

The fact that the helium-3 content, even at a depth of about 30 cm., is only 27 per cent smaller than near the surface of the Carbo meteorite confirms present-day views about penetrating power and the action on matter of cosmic rays[9].

Experimental details and discussion of our work will be published elsewhere.

Avidity of Terramycin and Aureomycin for Metallic Cations

It has been shown that the antibacterial action of 8-hydroxyquinoline is due to its ability to combine with ferrous, ferric and cupric ions accidentally present in the medium, the complexes thus formed being the true toxic agents[1].

It is therefore interesting to discover that terramycin and aureomycin also have high affinities for metallic ions. These affinities were put on a quantitative basis by potentiometric titration at 20° (with potassium hydroxide) of the chemically pure monohydrochlorides of these substances (0·001 *M*) in the presence of various metallic salts (0·0005 *M*) (0·00033 *M* for Fe^{3+}). Preliminary experiments had shown the formation, first of a 1 : 1-complex, and later, as the *p*H rose during titration, of a 2 : 1-complex, that is, one containing two molecules of the antibiotic to one atom of metal. Details of the titrations and the calculations were similar to those published for 8-hydroxyquinoline[2]. The results are given in the accompanying table, where K' refers to the 1 : 1-complex and K_s is the product of all the partial constants (of which a divalent ion has two and a trivalent ion three).

STABILITY CONSTANTS FOR METALLIC COMPLEXES

Metallic cation	Terramycin			Aureomycin		
	log K'	log K''	log K_s	log K'	log K''	log K_s
Fe^{3+}	9·1 (a)	7·2	22·0 (b)	8·8 (a)	7·2	21·6 (c)
Cu^{2+}	7·2 (a)	5·0	12·2	7·6 (a)	5·0	12·6
Ni^{2+}	5·8	4·8	10·6	(d)	(d)	(d)
Fe^{2+}	5·6	4·8	10·4	5·7	4·7	10·4
Co^{2+}	5·1	(e)	(9) (f)	4·8	(e)	(9) (f)
Zn^{2+}	4·6	(e)	(8) (f)	4·5	(e)	(8) (f)
Mn^{2+}	4·3	3·7	8·0	4·3	(e)	(8) (f)

(a) In these cases, the affinity was so strong that this first constant could only be obtained by back-titration with hydrochloric acid (4 equiv. in the case of Fe^{3+}).

(b) (c) These values include a log K''' of 5·7 and 5·6 respectively, three molecules of the antibiotics eventually becoming bound to this trivalent cation.

(d) Not attempted because of shortage of pure material.

(e) Precipitation of highly insoluble 2 : 1-complexes prevented readings being obtained.

(f) Deduced values (approximate).

Before these titrations could be undertaken, the ionization constants of the antibiotics had to be determined under similar experimental conditions. The terramycin was dried at 75° and 0·02 mm.; the aureomycin at 110° in air. The pK_a values for terramycin (0·001 *M*) were 3·10 (± 0·02); 7·26 (± 0·02) and 9·11 (± 0·03); and for aureomycin (0·005 *M*) 3·30 (± 0·02); 7·44 (± 0·01) and 9·27 (± 0·03), which are similar to the approximate values previously reported[3]. The values near 3 represent the ionization of cations, the others of anions. Trial calculations[4] showed that combination with metals required that the groups near pK_a 7 should be ionized but that those near 3 and 9 should not be ionized.

It is seen from the table that the constants for terramycin and aureomycin are almost identical within experimental error. These constants, and the order of preference for the various metals, are much the same as in the common amino-acids[4,5] with two important exceptions; (i) the position of Fe^{2+} is here elevated above its usual position between Mn^{2+} and Zn^{2+}, and (ii) Fe^{3+} is the most strongly bound ion, whereas amino-acids have little or no affinity for it[4,5].

It is interesting to note that the powerful antibacterial, 8-hydroxyquinoline, also combines preferentially with ferric iron; however, all the constants for terramycin and aureomycin are considerably lower. Moreover, because 8-hydroxyquinoline is inactivated by red blood cells, the comparison ought not to be pressed at this early stage of the investigation.

The copper and nickel complexes of these antibiotics were found to be green, the ferrous and ferric complexes red, and the others yellow. Unlike the free antibiotics, the complexes caused foaming when their solutions were agitated.

I thank Mr. E. P. Serjeant for technical assistance; Miss G. Hobby (of Chas. Pfizer and Co., Inc.) for a gift of chemically pure terramycin, and Dr. S. D. MacIsaac (of Lederle Laboratories Division of Cyanamid Products, Ltd.) for a gift of chemically pure aureomycin.

Isolation of Thorium B (Lead)-binding Substance from the Erythrocytes of Rabbit Blood

THE distribution of lead in blood fractions has been investigated by several workers. Recent studies made by using lead salts labelled with thorium B [1,2], and with radium D [3], showed that the lead is mainly held by the erythrocytes. The present communication deals with the isolation of the component mainly responsible for the uptake of thorium B by the erythrocytes.

The method of activating blood with thorium B was essentially the same as that described by Alexander[2]. An oxygen stream striking the surface of radiothorium was led into 20 ml. freshly drawn rabbit blood (heparin was used as an anti-coagulant) for 30 min. After activating, the blood was shaken for 30 min., since the maximum uptake of thorium B by the erythrocytes takes place during this process[1,2].

The active blood was centrifuged and the plasma removed. The erythrocytes were washed thrice with an equal volume of cold 0·9 per cent sodium chloride. The washed erythrocytes were chilled. To the chilled mass, an equal volume of cold distilled water and an equal volume of cold ether were added and mixed well and centrifuged. The clear hæmolysate was drawn out with a capillary. When the hæmolysate was dialysed against distilled water, it was found that 61 per cent of the thorium B present in it was in a non-dialysable form and the rest was in a dialysable form. To the hæmolysate at 0° C., one-third its volume of absolute alcohol at − 10° C. was added. It was kept in the ice chest for 30 min. and centrifuged. The precipitate was washed with cold 25 per cent alcohol until the last washings were colourless. The precipitate was found to be fifteen times more active than the same weight of hæmolysate. The precipitate was insoluble in water, in mineral acids and 0·9 per cent saline, but was soluble in $N/50$ sodium hydroxide up to about 0·5 per cent. The biuret, Millon–Nasse, xanthoproteic and ninhydrin tests were positive. With Benedict's reagent it gave a green precipitate; but no sugars were detected when the material was subjected to paper chromatography according to the method of Partridge[4]. It had a very weak blood group B specificity when tested according to the method of Bray *et al.*[5].

The precipitate was dissolved in 10 ml. $N/50$ sodium hydroxide and the protein was denatured by shaking with Sevag's reagent. It was shaken with 2 ml. of the reagent, a mixture of chloroform and *n*-butanol (10 : 1), for 30 min. and centrifuged. This operation was repeated several times until the supernatant solution gave no reaction with ninhydrin. The active component was precipitated by passing carbon dioxide for 10 min. into the protein-free supernatant solution. The precipitate, separated by centrifugation, retained all the activity present in the supernatant solution. The precipitate was insoluble in water but was soluble in $N/50$ sodium hydroxide. It was dissolved in 10 ml. $N/50$ sodium hydroxide, and a few drops of ammonium hydroxide were added and then precipitated with 20 per cent lead acetate. The lead salt was washed four times with 5 ml. of distilled water each time and once with absolute alcohol. It was dried *in vacuo* over anhydrous calcium chloride. The analyses of the lead salt, kindly performed by Dr. Simon (Heidelberg), were: C, 35·95; H, 4·88; N, 12·14; Pb, 26·08 per cent. 30 mgm. of the lead salt was suspended in 9 ml. of distilled water, acidified with $6N$ hydrochloric acid, hydrogen sulphide was passed to saturation and the suspension centrifuged. The supernatant solution was freed of hydrogen sulphide by bubbling nitrogen into it. It gave a positive Millon–Nasse reaction and a white precipitate with bromine water. It gave an orange colour with diazotized *p*-nitroaniline[6] and a blue colour with phosphotungstic–phosphomolybdic reagent[7]. These results suggest that the non-protein component is most likely a phenolic compound.

It appears from the above that the substance which is responsible for the uptake of 70 per cent of the non-dialysable thorium B present in the hæmolysate consists of a protein and a non-protein component. The non-protein component is most probably a phenolic compound.

Full details of this investigation will be published elsewhere. I wish to thank Prof. G. de Hevesy for his interest and encouragement during the course of this investigation.

Fixation of Radioactive Colchicine by Ehrlich Ascites Carcinoma Cells

IN this communication we wish to report briefly some results on the fixation of radioactive colchicine by the cells of the ascitic form of Ehrlich carcinoma, which is one of a number of tumours used by us in our work with radioactive colchicine.

Ehrlich ascites carcinoma, known since 1932 [1], and recently described in detail by G. Klein[2], consists of a suspension of discrete tumour cells floating in ascitic fluid. This type of tumour was found by us to be well suited to study the fixation of radioactive colchicine by individual cells, as their number can easily be counted, and the use of radioactive colchicine affords a sensitive and accurate method of measuring the amount of the drug present in tumour cells.

Table 1. NUMBER OF MOLECULES OF RADIOACTIVE COLCHICINE PER CELL IN RELATION TO INJECTED DOSES

Exp.	No. of animals	Dose of colchicine given (mgm.)	Total number of ascites cells (millions)	Molecules per cell (calculated)
1	1	0·5	146	4·6 × 10^{6}
	2	0·5	277	7·0 × 10^{6}
	3	0·5	226	7·2 × 10^{6}
	4	1·0	316	5·8 × 10^{6}
	5	1·0	400	5·1 × 10^{6}
	6	1·0	550	5·3 × 10^{6}
	7	1·5	380	7·3 × 10^{6}
2	1	1·24	436	10·0 × 10^{6}
	2	1·24	102	3·6 × 10^{6}
3	1	1·24	407	13·5 × 10^{6}
	2	1·24	480	17·9 × 10^{6}
	3	1·24	568	3·4 × 10^{6}

Table 2. Frequency Distribution of Radioactive Colchicine per Cell

	No. of molecules fixed by a single cell in a preparation:			
	0·1–5·0 × 10^6	5·1–10·0 × 10^6	10·1–15·0 × 10^6	15·1–20·0 × 10^6
0·5 mgm. colchicine injected	2	3	–	–
1 mgm. colchicine injected	2	19	4	3
1·2–1·5 mgm. colchicine injected	3	2	2	–
Total	7	24	6	3

White Swiss mice of 20–25 gm. weight bearing well-developed Ehrlich ascites tumours 7–10 days old were used. The radioactive colchicine was injected in a single dose intraperitoneally, thereby ensuring direct mixing with the ascites. The dose administered varied from 0·2 to 1·5 mgm. per animal. After four hours the animals were sacrificed, the ascites withdrawn with a syringe, and the cells counted by the red-cell counting technique. The cells were then separated from the fluid by centrifugation, quickly washed and recentrifuged; then they were extracted for their colchicine content by a method described previously by us[3].

Knowing the specific activity of the injected drug, we are able to calculate the quantity of colchicine fixed by the cells by measuring the radioactivity with an internal Geiger counter. Since the total number of cells present is known, the amount of colchicine fixed by a single cell is then calculated. By using Avogadro's number per gram molecular weight, we can express our results in number of molecules of colchicine fixed by individual cells.

From the examples given in Table 1, it can be seen that the number of molecules of radioactive colchicine per cell is in a large measure independent of the given dose and of the number of cells present in an ascites. From Table 2 it can be seen that the number of molecules per cell in the majority of cases (60 per cent) is 5·1–10·0 × 10^6.

The variations observed may be attributed in part to the experimental errors as well as to biological variations such as: (1) differences of absorption of colchicine by the walls of the peritoneal cavity; (2) differences in speed of excretion in faeces and urine; (3) differences in size of tumour cells present in ascites.

The small but constant quantity of colchicine fixed by the tumour cells is in accordance with the amount of colchicine needed to obtain a caryoclastic influence on cells, and probably gives a more accurate picture than qualitative methods used heretofore.

In a later and more extensive paper we shall give the results on the fixation of radioactive colchicine by Ehrlich ascites cells *in vitro*, and also results related to localization of colchicine in cells.

An Unidentified Growth-Factor for Yeast and Hyperthyroid Rats

We have already reported that acetone extracts of liver contain a factor that stimulates the growth of *Saccharomyces cerevisiae*[1], and of rats[2]. Liver dried at 110° and finely powdered is refluxed with dry acetone. The acetone extract is evaporated to dryness and the residue re-extracted with water. The growth-factor is thus obtained as a clear yellow solution having a pH of 4–5. It is heat-stable, dialysable and is not destroyed by acid or alkali. Part of inactive coloured impurities may be eliminated by passing the extract through a column of activated alumina or animal charcoal. The filtrate is still active and does not give the biuret or ninhydrin reaction.

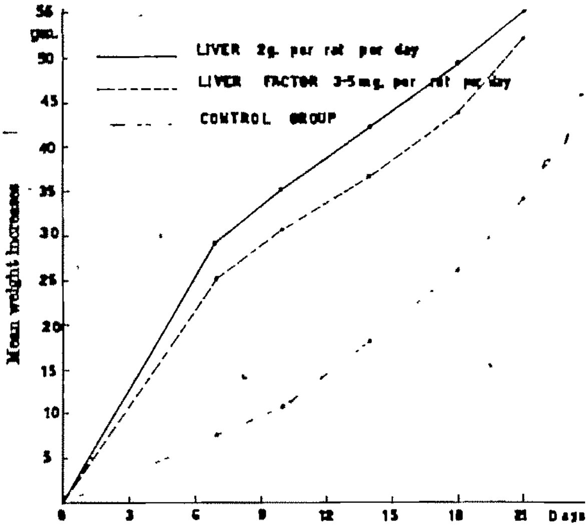
The effect of the factor on the growth of *Saccharomyces cerevisiae* was studied using the following basal medium: 0·7 gm. magnesium sulphate; 1·0 gm. potassium dihydrogen phosphate; 0·4 gm. calcium chloride; 0·5 gm. sodium chloride; 0·6 gm. ammonium sulphate; 0·1 gm. asparagin; 0·5 c.c. ferric chloride (1 per cent solution); 30·0 gm. glucose; 0·5 mgm. thiamine; 2·5 mgm. nicotinamide; 0·2 mgm. pyridoxin; 0·2 mgm. calcium pantothenate; 5·0 mgm. inositol; 0·01 mgm. biotin; water to 1 litre.

In experiments with an industrial yeast (strain 1d/30), we found that 15 μgm./c.c. of the factor doubled the growth after 24 hr. at 30°. The basal medium containing growth-factor was sterilized by steaming for 20 min. The inoculum was prepared by growing the yeast in the basal medium for 24 hr. at 30° and diluting to a concentration of 0·02 mgm. of yeast per c.c. 0·5 c.c. of this suspension was used for each test.

Male albino rats, just weaned, were kept on the diet advised by Györgyi[3] for the assay of vitamin B_{12}. This diet contains soya flour, sugar, vegetable oil, salt mixture and 0·25 per cent of thyroid powder; also a mixture of vitamins comprising thiamine, pyridoxin, nicotinamide, inositol, *p*-aminobenzoic acid and folic acid. After twenty days of depletion, the rats were divided into three groups of ten animals each. The first group served as controls. The rats of the second group received total aqueous extract of liver in a quantity corresponding to 2 gm. of fresh liver a day per rat. The animals of the third group received 3·5 mgm. of the growth-factor a day per rat. The accompanying graph gives the average of the results obtained in three different experiments.

The dose of 3·5 mgm. of growth-factor had an effect only slightly inferior to that of 2 gm. of liver. The effect can scarcely be due to vitamin B_{12}, which is insoluble in dry acetone. Moreover, vitamin B_{12} is destroyed by alkaline hydrolysis whereas the activity of our factor remains practically unchanged after prolonged boiling at pH 10; and our factor still caused a good growth response in hyperthyroid rats receiving a vitamin B_{12} supplement (40 μgm. per kgm. of diet).

That liver contains growth-factors in addition to those specifically identified has been known for some years. Recently, Yudkin[4] found that the growth of apparently normal children of two years of age was significantly improved when dried liver was added to a supposedly complete diet. Since our growth-factor is dialysable, it is unlikely to be identical with the factor reported by Dietrich, Monson and Elvehjem[5]. Since it gives no ninhydrin reaction, it is unlikely to be related to strepogenin. Since it does not give a nitroprusside reaction after treatment with



cyanide, it is improbable that it is related to thioctic acid[6]. However, more results must be accumulated before this factor can be correlated with or distinguished from those already reported in the literature, and also to determine whether it is really a rat-growth-factor or an anti-thyroid factor.

Tryptophane Metabolites in Human Urine

I HAVE already reported[1] that some human urine specimens made strongly alkaline yield distillates presenting spectroscopic and polarographic properties of *o*-aminoacetophenone. This was interpreted as indicating the presence of kynurenine in human urine, since (1) *o*-aminoacetophenone is not present in untreated urine, and (2) no substance other than kynurenine was known to behave in the way described under the condition of experiment. Tabone's interpretation[2], that the source of *o*-aminoacetophenone in human urine is tryptophane, was based on rather different and qualitative experiments.

Although this was made unlikely by quantitative considerations not described in the previous paper, the possibility was investigated further. Tryptophane does give *o*-aminoacetophenone, but in such small yields (about 0·1 per cent) that it could only be a minor source of inaccuracy. When added to urine, it gives even poorer yields, so that quantities between 1–10 gm. would have to be eliminated per day to account for the observed amounts of *o*-aminoacetophenone. On the other hand, it can be readily demonstrated that the urinary substance appearing after administration of 1·5 gm. tryptophane gives usually more *o*-aminoacetophenone than would all the tryptophane administered. The substance should therefore be regarded as a metabolite of tryptophane. In several specimens yielding *o*-aminoacetophenone equivalent to about 0·5 gm. tryptophane, only up to 10 mgm. per 100 ml. was detected by the method of Kraus[3]. Counter-current distribution curves indicate the presence of only one substance giving *o*-aminoacetophenone, and that substance has been found to show certain properties in common with kynurenine: (1) decomposition by alkali to *o*-aminoacetophenone; (2) the same distribution-coefficient in the solvent system (methanol–butanol–water); (3) paper chromatograms of partly purified urine preparations (using butanol–methanol–benzene–water) give a spot of the same colour and position as kynurenine, when developed either with ninhydrin or Ehrlich's reagent.

It is concluded that kynurenine is, without special dieting, present in human urine as the only important source of *o*-aminoacetophenone. The spectrophotometric determination of the latter could then be used for estimating urinary kynurenine, provided analytically satisfactory conditions can be found. The procedure originally described was improved with that purpose, to give almost quantitative (95 per cent) and constant recovery figures. The technique, which will be described in detail elsewhere, eliminates the interference of another substance and makes possible its simultaneous quantitative determination. This second compound is formed by the action of alkali from an acidic precursor which appears in urine especially after administration of tryptophane. Spectroscopic evidence indicates that it is a substituted aniline, but it will be referred to here as substance *B*. The concentration of both substances in normal persons and mental patients was very small (of the order of 0·2 mgm./100 ml. urine). Usually either kynurenine or substance *B* is excreted, and seldom both in comparable amounts. When animal protein is eliminated from the diet, excretion of kynurenine gradually decreases, often to be replaced by excretion of substance *B*. Of the vitamins administered, nicotinamide appeared to increase excretions of substance *B* without affecting that of kynurenine.

The study of the pathological significance of tryptophane metabolism is complicated by the influence of diet. However, a tendency to unusually high excretion of kynurenine was observed in a number of patients with conditions associated with cachexia, such as cancer. High excretion of substance *B* was found occasionally in these patients, but much more commonly in conditions associated with muscle inactivity.

The present study is being extended to the isolation, in sufficient quantities, and purification for classical analysis, of the urinary metabolites and their distillation products. The influence of diet is to be further investigated and results accumulated for correlating the analytical results with other laboratory findings and clinical diagnosis or progress of the disease.

I am indebted to the National Cancer Institute of Canada for the grant covering the expenses of these investigations.

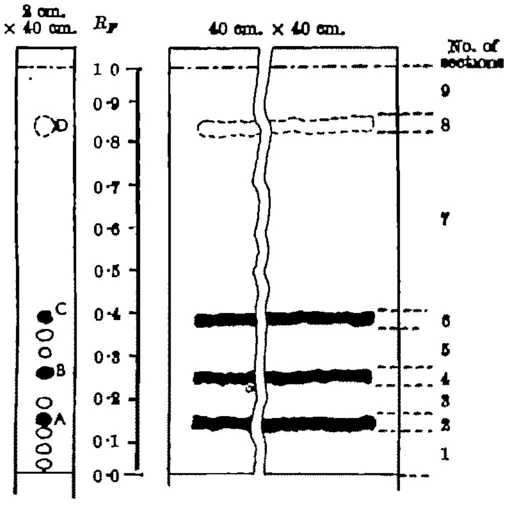
Substances in Bone-Marrow Extract accelerating Coagulation of the Blood

THOUGH previously it has been known that bone marrow contains a hormone-like substance which has an accelerating action upon the blood coagulation[1], its chemical nature has remained unclarified. We have now investigated this problem. Bone marrow from long tubular bones of domestic fowls, after removal of lipids with alcohol, acetone and ether, was extracted with physiological saline and then the extract was deproteinized with sulphosalicylic acid. After removal of excess sulphosalicylic acid with calcium carbonate, the filtrate was concentrated to a small volume. This filtrate showed a remarkable accelerating action on the blood coagulation.

Attempts were then made to separate the active fraction by several methods (absorption, fractionating precipitation with chemicals, etc.) and finally by paper chromatography. The active concentrate was chromatographed on No. 50 Tōyō filter-paper strip (2 cm. × 40 cm.) or on wider paper (40 cm. × 40 cm.) using water-saturated *n*-butanol as the developer (ascending method), and the spots or the bands were observed under ultra-violet light (2537 A.). As shown in the accompanying diagram, three spots, *A*, *B* and *C*, with R_F values of 0·13, 0·26 and 0·38 respectively, and another spot with R_F 0·86 showing a light purple fluorescence, were detected. Moreover, six spots with R_F values of 0·01, 0·05, 0·10, 0·16, 0·29 and 0·33 were detected with ninhydrin, indicating the presence of several amino-acids.

All these bands were cut out separately in nine strips and, after elution with water, each eluate was used in animal experiments for investigating its physiological action. The eluates from *A* and *B* bands distinctly accelerated blood coagulation, while the remaining seven fractions showed no activity.



Fraction *B*, which gave no sugar reaction, proved to be hypoxanthine (see table), because it showed the same R_F value as that of hypoxanthine in water-saturated *n*-butanol and in the two-phase solvent system of 5 per cent potassium dihydrogen phosphate and *iso*amylalcohol (2 : 1), and its ultra-violet absorption spectra in acid and alkaline solutions were identical with that of hypoxanthine. Fraction *A* separated into spot A_1, with R_F value 0·60, and spot A_2, with R_F value 0·69, on developing with the two-phase solvent system of Carter[2]; these R_F values are identical with those of inosine and guanosine respectively. Both fractions A_1 and A_2 gave the orcinol hydrochloric acid reaction[3] and yielded guanine and hypoxanthine respectively on hydrolysing with diluted sulphuric acid.

		Spot *A*		*B*	Guanosine	Inosine	Hypoxanthine	Guanine
		A_1	A_2					
(1) R_F values using *n*-butanol system		0·13	0·13	0·26	0·12	0·14	0·26	
(2) R_F values using two-phase system		0·60	0·69	0·53	0·60	0·69	0·53	
(3) R_F values after hydrolysis (*n*-butanol system)		0·05	0·26	0·26	0·05	0·26	0·26	0·05
(4) Orcinol hydrochloric reaction		+	+	−	+	+	−	
(5) Absorption maxima (mμ)	pH 1·0	250		248·5	250		249	
	7·0			250			250	
	10·0			261·5			261·5	

In physiological tests using a modified method of Sahli–Fonio with rabbits as test animals, authentic samples of hypoxanthine and guanosine distinctly accelerate the blood coagulation in doses of 200 γ for a rabbit weighing 2·0 ~ 2·5 kgm. The activity of inosine seems a little weaker than that of hypoxanthine or guanosine.

Sub-Diploid Chromosome Variation in Man and other Mammals

THE existence of sub-diploid chromosome numbers in the somatic tissues of mammals has for long been a matter of controversy. This had centred around several earlier reports of the normal occurrence of many somatic cells with less than the diploid number of chromosomes. The controversy has again been recently revived by reports[1] that the human uterine endometrium normally contains cells with varying numbers, ranging from 4 to 104, of chromosomes. The highest frequency peak of these numbers is supposed to lie in cells with 20–25 chromosomes, with a much lower peak in cells with 45–50 chromosomes. It is also suggested that this type of chromosome variation may be a distinct characteristic of warm-blooded animals.

The existence of cells with more than the diploid number of chromosomes would not be a unique occurrence, as different degrees of polyploidy can be present in various tissues. It has also been shown that genetic abnormalities of mitosis can produce some sub-diploid variation[2]. But the normal existence of such a large proportion of sub-diploid and particularly of sub-haploid cells within the same tissue would be a fact of special interest.

In order to check on this reported chromosome variation, I have examined the chromosome numbers in cells of the human uterine endometrium. As further controls, the normal uterine endometrium of *Rattus norvegicus* (laboratory albino rat) with $2n = 42$, and of *Microtus agrestis* (short-tailed bank vole) with $2n = 50$, have also been examined. The rodent *Microtus agrestis* is especially favourable for somatic chromosome studies since the two sex chromosomes are considerably larger than any of the 48 autosomes and they can be readily identified during the stages of mitosis[3].

In both the present and Timonen's[1] observations, the cytological study was based on the use of Feulgen squashes. This technique can give satisfactory results for mammalian chromosomes[4]. But in making such preparations, one has to be very careful that the cells have not been damaged by the squashing. In the scoring of chromosome numbers, I have therefore taken particular care that no damaged cells were included. All chromosome counts have been made with an accuracy of about 5 per cent of the chromosomes or even better. Fifty cells were scored in each of the three species, and these have shown no variations from the normal diploid chromosome numbers. In addition, it was clear from the appearance of many dividing cells which could not be so accurately counted that there is no extensive sub-diploid variation.

Some reductions in chromosome number as a result of such mechanisms as lagging, non-disjunction, or an occasional multipolar spindle, may normally occur in some somatic cells. Multiples of the diploid number may also occur. But there is no indisputable evidence of extensive sub-diploid variation as the usual constituent of normal somatic tissues.

An Irreversible Choline-esterase Inhibitor in White Clover

In the course of a study of the decomposition products of radioactive octamethylpyrophosphoramide in white clover (*Trifolium repens*, strain *S*100) it was found incidentally that extracts from clover, whether previously treated with this compound or not, inhibited choline-esterase *in vitro*.

Clover samples were macerated with water, the macerate extracted with chloroform (equal volume) and the chloroform extract evaporated nearly to dryness under vacuum. Water was then introduced, the remainder of the chloroform distilled off, and the aqueous solution filtered free of the chlorophyll precipitated. The anticholine-esterase activities of the aqueous products from untreated clover were found by Michel's method[1], using freeze-dried plasma. The aqueous products from treated clover were evaporated under vacuum in the presence of trichloroethylene, thus obtaining chlorophyll-free solutions in this solvent of the chloroform extractables without subjecting them to a temperature above 20° C. or to prolonged contact with water. The trichloroethylene solutions were then chromatographed on a kieselguhr column, with a water standing phase and a 30 per cent chloroform : 70 per cent trichloroethylene (v/v) moving phase. The eluent fractions were tested for anticholine-esterase activity as before.

The total anticholine-esterase activity is expressed as the volume of solution in millilitres extracted from 1 kgm. of clover inducing 50 per cent inhibition in a serum solution after incubation for 30 min. at 25·6° C. In these units, four untreated samples gave values of 3,640, 4,550, 640 and 32*; two treated samples, 2,140 and 10,620; and volumes of solvents equivalent to those used in the extractions, 20–30. There are considerable variations. Most are probably to be accounted for by absorption on the chlorophyll precipitated when the chloroform is removed. It was later discovered that, unless special precautions are taken, up to 80 per cent of a low concentration of octamethylpyrophosphoramide may be absorbed by the chlorophyll in this way, and that the amount absorbed is very variable. Probably the inhibitor is similarly absorbed. The starred value is, however, very much lower than the rest. The sample of clover for which this value was obtained came from another field of *S*100 clover in a very different state of growth, and yielded little or no inhibitor.

One active sample was tested by Mr. K. P. Fellowes for *in vitro* activity against human and rat red cell choline-esterase, and for reversibility towards rat cells by the method, slightly modified, of Aldridge[2]. It was about equally active against human and rat red cells as against human plasma, and showed no signs of reversibility after washings equivalent to $6 \cdot 4 \times 10^7$ dilution.

The inhibitor from the treated samples was eluted from the column before the octamethylpyrophosphoramide or any other phosphorus-32-containing band appeared. It therefore separates more readily than these compounds from water into the organic solvents used. Its anticholine-esterase activity was only reduced to a third by the action of *N* sodium hydroxide for 30 min. at 15° C., and was not observably affected by storage in water for one week.

If this compound can be absorbed by animals eating large quantities of clover, it might be expected that they would show some ill-effects. Bloat in sheep and cattle is attributed to cyanogenetic compounds produced by several varieties of clover[3]. It is certain that the substance we have discovered does not inhibit choline-esterase by producing cyanide, as *M*/100 potassium cyanide only induces 20 per cent inhibition in plasma choline-esterase under our experimental conditions; but this does not rule out the possibility that the choline-esterase inhibitor is identical with one of the cyanogenetic compounds. Thus clover may in some cases produce signs of anticholine-esterase poisoning as well as cyanide poisoning. We think, therefore, that these observations may have some relevance to bloat.

Free Xylose in Fruits

AN investigation of the carbohydrates present in the Victoria plum has revealed the presence of small amounts (c. 0·1 per cent fresh weight) of free xylose in the juice of ripe and immature fruits. The origin of this sugar is uncertain; it may arise from enzymic hydrolysis of a xyloside, but we consider this unlikely.

The xylose was isolated by maceration of the plum mesocarp, followed by dialysis against distilled water. The dialysate, containing the free sugars, was evaporated to a syrup *in vacuo*, and the xylose isolated by partition chromatography using a cellulose column[1].

The xylose was characterized by paper chromatography (Whatman No. 1 paper was employed) using as solvents ethyl acetate – acetic acid – water (9 : 2 : 2), *n*-butanol – pyridine – water (10 : 3 : 3), and phenol–water (phenol saturated with water). The chromatograms were developed by spraying with 4 per cent anisidine hydrochloride in *n*-butanol[2].

Further proof of identity was obtained by the preparation of a dimethyl acetal dibenzylidene derivative.

Sufficient material was not available for accurate optical measurements, though a preliminary examination showed that it exhibited a small dextrorotation.

Evidence has also been obtained of the existence of free xylose in other varieties of mature plum, damson and quince, and Dr. A. E. Flood and his colleagues have detected it chromatographically in young apple and pear shoots, and in the leaves of potato[3].

It is hoped to continue the investigation when further supplies of fruit are available. We are indebted to Dr. J. K. N. Jones for his advice and interest during this work.

Amino-Acids in Phloem Sap and their Excretion by Aphids

SOME results of the application of paper chromatography to the detection and estimation of amino-acids and sugars in the honey-dew excreted by aphids and coccids have been published recently by Gray[1], Maltais and Auclair[2], and others. What has remained obscure is the relation between the composition of the honey-dew and that of the plant sap on which these insects are feeding.

The determination of the composition of phloem sap, which is the normal food of aphids, was undertaken in 1950. The phloem sap of two- to four-year-old stems of *Salix* spp. was collected as it exuded through the severed mouthparts of the aphid, *Tuberolachnus salignus* (Gmelin), by the method outlined by Kennedy and Mittler[3]. Its chemical composition was compared with that of the honey-dew excreted by aphids feeding on the same stems at the same time. When equal volumes of freshly collected phloem sap and honey-dew were run side by side on chromatograms, it was found that each of the amino-acids which could be detected in the honey-dew was present in the phloem sap. All the amino-acids were in a higher concentration in the phloem sap than in the honey-dew. The chromatograms did not suggest that there was any differential absorption by the aphid of amino-acids from the sap. Acid hydrolysis of samples of sap and honey-dew did not result in any increase in the number or quantities of the amino-acids, other than aspartic and glutamic acids, at the expense of their amides. Quantitative determinations of the total nitrogen in the sap and honey-dew also showed that, over a considerable range of concentrations, the amounts of total nitrogen in the sap were always in excess of those present in the honey-dew.

These results suggest that the nitrogenous matter ingested by an aphid is in the form of free amino-acids and amides, which are usually in excess of the aphid's requirements. The free amino-acids detected in the honey-dew seem to come directly from the ingested sap, and are not to be regarded as products of protein breakdown or of the fixation of atmospheric nitrogen supposedly through the agency of the aphid's symbionts[4].

It was further found that the number and the amount of amino-acids in the honey-dew depend on the extent to which these amino-acids are present in the phloem sap of the plant. The amino-acid composition of the phloem sap depends in turn on the developmental stage of the plant. As shown by Kennedy and Booth[5], certain leaf-feeding aphids colonize growing and senescing leaves in preference to leaves in an intermediate, fully functioning condition. The greatest variety and abundance of amino-acids in the phloem sap of the willow stems were found during the growth and senescence of their foliage. The following amino-acids and amides could then be demonstrated readily both in phloem sap and in honey-dew: aspartic acid, glutamic acid, serine, threonine, alanine, valine, leucine and/or *iso*leucine, phenyl alanine, asparagine, glutamine and, possibly, γ-amino-butyric acid. During the period after growth had ceased and before leaf senescence set in, however, all that could be detected were small amounts of aspartic acid, glutamic acid and their amides.

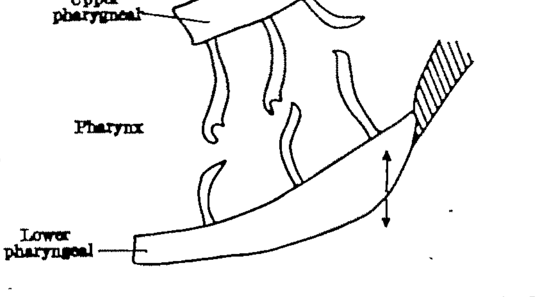
Feeding Mechanism of the Cichlid Fish, *Tilapia esculenta* Graham

THE food of *Tilapia esculenta* consists mainly of phytoplankton[1], although zooplankton and insect larvæ[2] have occasionally been recorded. Diatoms are the most important food elements of the phytoplankton, particularly the filamentous *Melosira*. In the evidence for his 'Law of the Distribution of the Ngege', Graham[3] concluded that the simple gill-rakers of *T. esculenta* were not adapted for straining phytoplankton and that consequently the species obtained its food from the living layer of diatoms in the bottom deposits. Recent work[3] on the feeding habits of this fish have shown that a considerable proportion of the diatoms taken must be considered as truly planktonic, and that the fish strains them from the water. The outer series of gill-rakers on the first branchial arch are relatively coarse (see plate in Graham[4]); but those of the inner series on this arch and both series on the three succeeding arches are finer, especially on the inner aspect of the fourth arch. The interdigitation of the gill-rakers forms a sieve between the arches which could retain coarse particles of food, for example, copepods, but not the individual organisms of the phytoplankton commonly recorded from the stomach. Some other method of food collecting must therefore be operative. A study of the histology and anatomy of the pharynx and buccal cavity has suggested a method whereby such fine food can be retained and swallowed.

The dorsal epithelium of the bucco-pharyngeal cavity is thrown into a number of low folds, thus increasing the surface area. Mucous cells occur in all areas of the oral and pharyngeal epithelium but are most concentrated and numerous along the posterior mid-dorsal surface of the mouth and pharynx and on the gill-arches.

Both the upper and lower pharyngeal bones are situated in the posterior part of the pharynx immediately anterior to the opening of the œsophagus, the passage between them sloping upwards at a sharp angle from the floor of the pharynx to the œsophagus. The lower bone is a broad triangular plate with the apex directed anteriorly; immediately above it, and opposing the greater part of its dentigerous surface, lie the paired upper pharyngeals, which are separated from one another by a narrow ridge of secretory epithelium. All three bones are beset with very numerous and fine teeth. The majority of the teeth on the lower pharyngeal are without distinct cusps and have the distal part strongly recurved (see diagram). Only in the most posterior rows are they distinctly cuspidate and erect. However, most of the upper pharyngeal teeth are markedly cuspidate, having a small posterior cusp and a larger, posteriorly curved cusp on the anterior side; together they form a hook-like tip directed towards the œsophagus (see diagram). Sets of small muscles move the upper pharyngeals antero-posteriorly and, to a lesser extent, laterally. Observations on the living fish show that this movement can be synchronous with, or independent of, the normal respiratory movements. The position of the lower pharyngeal can be altered so that its toothed surface can be brought into closer apposition with the upper pharyngeal teeth.



Diagrammatic representation of the pharyngeal bones and teeth of *Tilapia esculenta*. Teeth representative of anterior, middle and posterior tooth rows. Arrows indicate movement of bones when feeding

When feeding, it appears that the suspended phytoplankton is drawn into the buccal cavity, where it becomes entangled with the copious mucous secretion. Within the buccal cavity, turbulence, due to the intermittent nature of the inhalant current, would assist in this mixing. The mucus and food aggregates are carried posteriorly, but are prevented from escaping with the outgoing current by the gill-rakers. It is considered that the gill-raker sieve is sufficiently fine to prevent the free passage of these aggregates. Collection and concentration of the food apparently takes place in the posterior part of the pharynx, where the aggregates become entangled in the anterior teeth of the lower pharyngeal bone. When the upper pharyngeal bones are moved backwards, the hooked crowns of their teeth pass between the teeth of the lower bone and rake the mucus and entangled phytoplankton towards the œsophagus. Since the food is drawn through the lower teeth, large elements tend to be broken into smaller fragments. This explains the almost uniform lengths of the *Melosira* filaments which are found in the stomach of any one individual[1].

Even if the fish do feed on the bottom deposits—and there is evidence that they may occasionally do so—the mechanism described above will still be operative.

The opinion has been expressed[1] that the stomach of *Tilapia esculenta* may function merely for the storage of food prior to its digestion and assimilation in the duodenum. Histological examination of the stomach shows that the mucosa is well supplied with gastric glands similar to those found in other fish, and it seems likely that the initial stages of digestion occur in the stomach.

Isolation of Intertidal Animals by Sea Barriers

In recent surveys of the Irish coast, we have established that several intertidal animals common in south-west Britain are not present in Ireland. The most notable absences are those of the barnacle, *Balanus perforatus* Bruguière, and the limpet, *Patella intermedia* Jeffreys (= *P. depressa* Pennant), both of which are found on the south coast of England west of the Isle of Wight, and off South Wales. *Balanus perforatus* extends only to the southern shores of Cardigan Bay[1], but *Patella intermedia* is found at least as far north as Holyhead; yet both are altogether absent from Ireland. Neither of these species has been suspected hitherto of being a recent immigrant to the British Isles; but of two other species which we failed to observe in Ireland, namely, the barnacle, *Elminius modestus* Darwin, and the bryozoan, *Bugula neritina* (L.), the former is known to be, and the latter thought to be, a ship-borne immigrant[2].

It seems most improbable that any of these species could be excluded from Ireland on account of climatic or hydrographic factors. While all are relatively warm-water forms, they extend to parts of the British coast (St. George's Channel, and, in the case of *Elminius*, the North Sea) which are subjected to colder winter sea and air temperatures than prevail over much of the south and west Irish coastline. The milder character of the Irish coast is indeed well illustrated by the distribution of certain intertidal animals which are not present on the colder parts of the British coast, and which, to some extent, may be regarded as indicators of climatic conditions. In order of apparent increasing tolerance of lower temperature or wider ranges of annual temperature these are: the sea urchin, *Paracentrotus lividus* (Lamarck), the top shells, *Osilinus lineatus* (da Costa), and *Gibbula umbilicalis* (da Costa), and the barnacle, *Chthamalus stellatus* (Poli). *Paracentrotus lividus*, although abundant throughout western Ireland, is virtually absent from south-west England, and of the other species, none is found in greater abundance in south-west England than in south and west Ireland.

It is tempting to suggest that *Balanus perforatus* and *Patella intermedia* may be representatives of a fauna which migrated northwards in post-glacial times, extending its distribution to Britain while the coastline was continuous with that of Europe, but failing to colonize Ireland before the land bridge was severed. There can be little doubt that existing deficiencies in the Irish land fauna and flora result from the existence of the sea barrier[3]. It is possible, however, that these species have been introduced to Britain within historical times, *Balanus perforatus* in particular being sometimes found on ships' bottoms. It is also possible that *Patella intermedia* is a recently evolved form[4]. Whatever explanation is adopted, it is difficult to escape the conclusion that even fairly narrow seas offer a barrier to predominantly intertidal animals.

The recent immigrant, *Elminius modestus*, affords a most valuable example of this effect in operation at the present time. Although now abundant on the eastern side of the Irish Sea, it has not yet appeared in Ireland, nor seriously invaded the Isle of Man, which at its nearest point, Ramsey, is only thirty-one miles from the nearest recorded locality for *Elminius* on the English coast. (To date, only two specimens have been found in the Isle of Man, both of them at Ramsey.) Yet in a coastwise direction the species has spread southward from Morecambe at a rate of approximately 20–25 miles a year, and now extends from Cumberland to Anglesey.

A greater spread along the coast is to be expected, because the tidal streams and the residual currents are obviously stronger parallel to the shore than at right-angles to it. Moreover, the establishment of a new community of sessile, or nearly sessile, creatures, which are either cross-fertilizing or have the sexes separate, requires the attainment of a minimum population density before the community can maintain itself. This is especially true of barnacles, which, though hermaphrodite, appear generally to be incapable of self-fertilization[5]. In contrast, certain molluscs, such as the oyster and the slipper-limpet, while normally protandrous hermaphrodites, seem to be occasionally capable of self-fertilization[6]. The threshold density of population for self-maintenance can be reached without difficulty on substrata adjacent to an established community; but at greater distances the larvæ become progressively more thinly dispersed. A critical distance must exist, related to the current system and the duration of the free-swimming stages, beyond which the rate of settlement of the larvæ is normally insufficient to reach the minimal population density within the life-time of an individual. The chance of colonization by a purely intertidal organism across a sea barrier wider than this becomes vanishingly small. From observations on the spread of *Elminius modestus*, which has a free-swimming life of about three to four weeks, and matures in the same season, it would appear that the critical distance along the North Wales coast would be at most 30–40 miles; this value is exceptionally interesting in comparison with calculations, based on salinity correlation coefficients[7], which indicate that the residual current in this area has a velocity of approximately 0·9 mile a day. However, this particular species can be transported in large numbers by shipping or on floating objects, so it is capable of reaching new areas far outside this critical range[8].

It is concluded that comparatively narrow sea barriers must be of importance in the distribution and evolution of predominantly intertidal animals and plants, the biogeography of which would appear to have much in common with that of terrestrial rather than that of entirely marine organisms.

We wish to thank the Royal Society for a grant in aid of the investigations, and Dr. J. A. Kitching, who has confirmed some of our absence records from his own exhaustive studies in the Lough Ine area.

Ozonium Wilt of Guar and Cucurbit Plants in Bihar

GUAR plants (*Cyamopsis psoraloides*) are widely cultivated in Bihar as fodder, and the green pods are also used as vegetables. A serious wilt of guar was noticed in restricted areas during September 1952 at several places, and as much as 20–25 per cent of the plants contracted the disease. The infected plants first showed yellowing of the leaves, loss of turgidity and finally wilted away. Examination of the collar portion of the plants showed thick strands of hyphæ enveloping and girdling the shoots and developing numerous chocolate-brown sclerotia 1–1·5 mm. in diameter. The hyphæ were compacted into definite strands of rhizomorphs unlike those of a similar fungus *Sclerotium rolfsii* Sacc. The fungus causing wilting of guar is identical with *Ozonium taxanum* Neal and West. var. *parasiticum* Thirumalachar[1].

Wilting of shoots of *Cucurbita maxima* incited by the same fungus was noticed in several places. On the plants the vines were parasitized and killed by the fungus, which was apparently developing from the soil surface and possessing well-developed rhizomorphs. The portions of the shoots extending upwards from the place of infection wilted away and caused considerable losses to the growers. Portions of fruits in contact with the soil often rotted due to infection by the fungus. The strands of rhizomorphs crept up the fruit surface and after penetrating the tissue incited a wet rot. Since the sclerotia have been found to be viable for long periods in the soil, the possibility of the fungus building up in proportion and causing immense losses in these economic crops is great. Control measures are being investigated.

A Method for computing the Optimum Size-Limit for a Fishery

In an exploited fishery, one of the main functions which a properly selected size-limit can have is to ensure that the weight of the yield is the maximum possible, with minimum losses due to unrealized growth or natural deaths. Where all fish reaching the limit are caught, determination of the correct value for the limit to achieve this purpose is theoretically simple, although in practice the basic data regarding growth- and mortality-rates, on which the determination is based, may not be easy to obtain. Such cropping conditions are found only in fish-farming. Normally, in fish stocks subjected to either angling or commercial fishing, only a small proportion of the fish reaching the limiting size pass into the catch. This causes a modification to the optimum value of the limit. Ricker[1] has pointed out that the size-limit must be less under these conditions than when cropping is complete, and has described a method for computing the optimum value when full data regarding growth, natural mortality and cropping-rates are available.

Results of practical value can be deduced from more easily obtainable data by making use of the property that, when the limit is at the optimum value, a very small change in the limit does not cause the size of the total catch to alter. A fish stock can be considered to consist of a number of groups of fish all of which are of the same size at any instant. Assume that cropping begins at the time T when the number of fish in the group which is just passing the limit is N, and that a fraction K of these fish are afterwards caught and have at time of capture a mean weight V, then the total weight of the crop obtained from these fish is KVN. If the cropping point is now made earlier by an interval dt, then the number of fish in the group at the cropping point will now be $N + dN$, where $dN = Nm.dt$ and m is the instantaneous natural mortality-rate. If the average weight of these fish is W and the instantaneous cropping-rate for fish of this size is c, then when the time T has been reached, $Nc.dt$ will have been caught weighing $WNc.dt$. The number of survivors to time T is therefore now $N - Nc.dt$. Since there is no reason for supposing that the conditions under which they are cropped have been changed, these survivors will give a yield of $KVN(1 - c.dt)$. The total crop from the original group when cropping begins at $T - dT$ is therefore $KVN(1 - c.dt) + WNc.dt$. When T is the point of commencement of cropping for maximum yield, this equals KVN and therefore:

$$KVNc.dt = WNc.dt,$$
$$\text{or } W = KV.$$

Thus, when the limit is that which gives the maximum yield, the weight of the typical individual fish at the limit is the product of the average weight of fish in the catch and the proportion of the fish passing the limiting size which are ultimately caught. Since this applies to each group in the population, it applies also to the population as a whole.

These two statistics are relatively easily measured in practice where adequate catch data are obtainable, the former by direct weighing of a sample of the catch, and the latter by obtaining recapture records for fish marked and liberated at the limiting size. The testing of the correctness of an existing limit can be done directly from these two measurements. If an existing limit is found to be incorrect, a first approximation to the correct value is immediately obtained. This approximation is subject to errors caused by the effect of the existing limit on both V and K. In many cases the original catch data will be in a form which will allow fairly accurate evaluation of V for a proposed new limit, and some indication of the effect on K may also be obtained. Application of these corrected values, if necessary in more than one step, should often enable a value of the optimum limit to be obtained which would be sufficiently accurate for experimental trial.

An estimated value cannot be obtained from data based on an existing limit if K is equal or close to unity, since in this case the average weight of the fish caught is automatically equal to the weight of a fish of the limiting size, and the approximation obtained is equal to the existing limit.

A Suggested Alternative to the Correlation Coefficient for testing the Significance of Agreement between Pairs of Time Series, and its Application to Geological Data

It has for some time been realized that the ordinary test of significance of the correlation coefficient cannot be applied indiscriminately to pairs of time series, since serially adjacent observations are not in general independent. Tests of significance of the correlation coefficient have therefore been developed which are designed to make allowance for the effect of autocorrelation[1].

An alternative measure of agreement, which sacrifices some of the advantages of the correlation coefficient for the sake of simplification of the necessary test of significance, is proposed here. It is not a dimensionless quantity, and therefore it can only be used with pairs of time series which have approximately the same mean and variance. (This requirement can be met by a linear transformation when necessary.)

Consider two time series, $p_1, p_2, p_3, \ldots p_r, \ldots$ and $q_1, q_2, q_3, \ldots q_r, \ldots$, corresponding terms in each series being denoted by the same suffix. We define the cross-difference product E by the relation :

$$E_{r,r+1} = \tfrac{1}{2}\{(p_r - p_{r+1})^2 + (q_r - q_{r+1})^2 - (p_r - q_r)^2 - (p_{r+1} - q_{r+1})^2\} \quad (1)$$

$$= (p_r - q_{r+1})\,(q_r - p_{r+1}). \quad (2)$$

If there are $2n$ terms in each time series, n independent values of E may be calculated, each being based on two adjacent terms in each series. The mean value of E, given by :

$$\frac{1}{n}\Sigma E = \frac{1}{n}(E_{1,2} + E_{3,4} + E_{5,6} + \ldots + E_{2n-1,2n}) \quad (3)$$

will be positive if, on the average, corresponding p and q terms differ less from each other than they do from their neighbours in the same series. In the contrary case, the mean will be negative. For a pair of independent random series, the individual values of E will tend to be distributed symmetrically about zero mean. We may take this as our null hypothesis. The significance of an observed positive mean value of E may then be tested by means of Student's t-test, or if n is sufficiently large, the labour of computing the values of the individual terms of equation (3) may be dispensed with ; and instead the frequencies of positive and negative signs of E may be found by merely inspecting the data, and the significance of an observed excess of positive signs tested by means of Pearson's χ^2.

A significant result will indicate that there is a relationship between the two series which cannot reasonably be attributed to a chance coincidence. It is easy to see that positive first-order autocorrelation is without effect upon the significance test, since the stronger it becomes the greater the resemblance between the two series necessary to give a positive mean value of E.

The cross-difference product E provides a simple means of testing the significance of the observed agreement between a pair of geological sections for which numerical data of any kind are available. Chronologies based on tree-rings and glacial varves are of particular interest, owing to the criticisms of principle which have been levelled against them. As an example of the method, I have taken measurements of two series of varves figured by Reeds[2] from Haverstraw, N.Y. (736 varves), and New Haven, Conn. (343 varves). These localities are about fifty miles apart. In order to eliminate long-term trends of purely local importance, I have taken the first differences of the actual varve thicknesses. There is a strong negative first-order autocorrelation in both series of first differences, which would seriously bias the mean value of E if equation (3) were used. I have therefore taken the values of E based upon alternate first differences, as follows :

$$\frac{1}{n}\Sigma E = \frac{1}{n}\{(p_1 - q_3)\,(q_1 - p_3) + (p_5 - q_7)\,(q_5 - p_7) + (p_9 - q_{11})\,(q_9 - p_{11}) + \ldots, \text{etc.}\} \quad (4)$$

The first differences of the two varve series of 343 pairs of varves give 85 independent values of E, of which 60 are positive, 15 are negative and 10 are zero. This gives $\chi^2 = (60 - 15)^2/(60 + 15) = 27{\cdot}0$. This value is not covered by the tables, but is far beyond the 0·001 level of significance. Alternatively, the standard error of the binomial gives a value of $P < 0{\cdot}000001$.

It will be realized that because Reeds chose the best out of about four hundred alternative ways of matching his varves, the above value of P must be multiplied by 400. The true value of P is thus approximately 0·0004, which is still strongly significant, so that we are bound to conclude that the observed agreement of the two varve series is very much greater than could be obtained by attempting to match up two unrelated time series.

In general, if P_n is the level of significance given by the test of the null hypothesis, and N is the number of alternative choices available in matching the varves, then the true level of significance of the result is given by $P_t = NP_n$. A varve correlation which is based on independent evidence, such as a band of volcanic ash, will have $N = 1$ and $P_t = P_n$.

A New Method of testing the Pathogenicity of *Phytophthora fragariæ*

In a study of the influence of soil moisture and pH on red core disease of strawberries, caused by *Phytophthora fragariæ*, Hickman, Hickman and English[1] described an infection technique with plants in pots that gave consistent and rapid results, and the method was used for distinguishing physiological races[2].

Recently, we have developed a new method which not only shortens the experimental period from seven weeks to twelve days but also provides a yet more severe test of resistance. Essentially it involves mass inoculation of the roots by immersing them for about twenty-four hours in an active zoospore suspension of the fungus. The plants are then potted up in sand and left for a period of about twelve days. By this time, in susceptible varieties, infection is so extensive as frequently to cause pronounced wilting. The zoospore suspension is conveniently prepared by immersing large colonies of *P. fragariæ* in non-sterile pond water. The fungus is grown on plates of bean agar[1] until the mycelium has almost reached the edge of the plates. The colonies are then cut out, taking care not to sever the tips of the actively growing hyphæ, and supported on glass-rod frames in dishes of pond water so that they are just submerged. Two such colonies have been used to 500 ml. water. In 24–48 hr., at laboratory temperature (10–15° C.), a dense, opaque fringe of sporangia has grown out from the colony margin and, in addition, numerous sporangia have been produced from the under surface of the colony, particularly towards its edge. Sporangial formation and liberation of zoospores continues for two to three days.

This technique not only dispenses with the pre-inoculation period of one month, used in the original method, during which the potted runners were allowed to root, but economizes still further on space and labour. Thus, after immersion in zoospore suspension, the runners are planted five to a pot, instead of one. Lastly, the use of sand for potting simplifies the removal and washing of roots for examination.

Dielectric Relaxation Processes in Ethanol

The existence of secondary regions of dielectric dispersion for a number of polar liquids has been inferred by several workers from radio-frequency and microwave dispersion data, as these extrapolate at high frequencies to values considerably larger than the square of the refractive index. Notable examples of this behaviour are water and the lower aliphatic alcohols[1], for which at temperatures from 0° to 60° C. the principal dipole dispersion region lies in the range of centimetre to metre wave-lengths. Saxton[2] has discussed the question in detail for water, methyl and ethyl alcohols, and found that his data, together with results in the wave-length region 50–150 μ, could be described by postulating a damped resonance dispersion in the millimetre wave-length region.

Results in this laboratory[3] for *n*-propanol, however, show that much of the discrepancy, at least at low temperatures, is explained by the existence of secondary relaxation-type dispersions which fall in the range of radio- and even audio-frequencies at temperatures below − 100° C. A similar situation has been found in more recent studies of ethanol and ethanol–water solutions, which we report in this preliminary note because of the obvious implication that such dispersion processes are probable in alcohols generally, and quite possibly in other polar liquids as well.

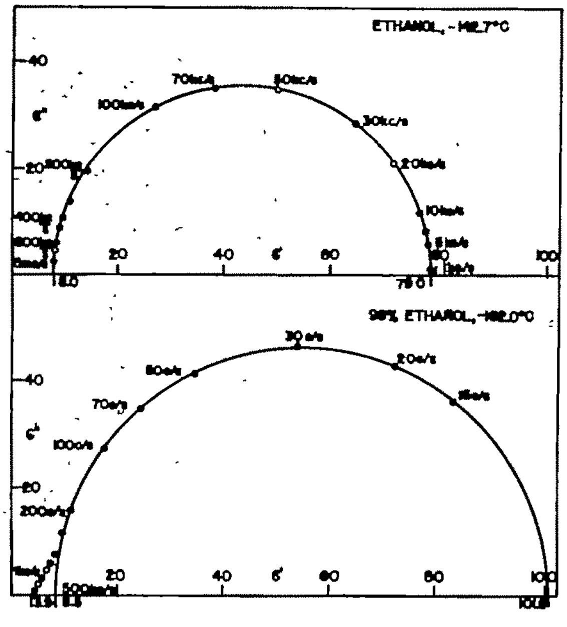

Fig. 1. Loci of the real (ε′) and imaginary (ε″) dielectric constants for ethanol at − 142·7° C., and 99 per cent ethanol at − 162° C. Frequencies of measurement are indicated

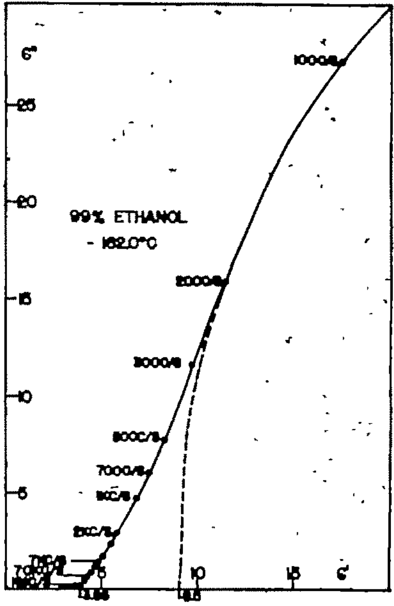

Fig. 2. High-frequency portion of the complex-dielectric constant locus for 99 per cent ethanol at − 162° C. The dashed curve is the extrapolation of the low frequency locus (cf. Fig. 1)

Our measurements in the range 15 c./s.–5 Mc./s. show that the principal dielectric dispersion is quantitatively described by a simple dielectric relaxation process at temperatures below − 120° C., as the semi-circular complex loci of Fig. 1 illustrate. The high-frequency intercepts of 8·0 and 8·6 for the real part ε′ of the dielectric constant are seen, however, to be much larger than the square of the refractive index (n^2), in agreement with Saxton's conclusion[2] from measurements at room temperature.

Addition of 1 per cent by weight of water to ethanol makes possible considerable supercooling, and a second dispersion is observable at radio frequencies below − 147° C., as shown in Fig. 1 and in more detail in Fig. 2. This dispersion moves rapidly to lower frequencies on further cooling and its extent increases. Both effects are consistent with a relaxation rather than a damped-resonance type of polarization. Some evidence has been found for still a third distinct dispersion which would bring the dielectric constant even closer to the optical value of about two.

We surmise that the second dispersion is the counterpart of the behaviour found at millimetre wave-lengths for methanol and ethanol at room temperature, but that it is properly interpreted as a relaxation rather than damped resonance polarization. The possibility of more than one distinct relaxation process seems to have been largely overlooked in the past, possibly because of the tendency to think of molecular orientations in terms of simple dipoles.

A simple explanation of the observations can be given in terms of the OH and O*R* group moments of an alcohol ROH that the higher-frequency dispersion results from orientations of OR moments consistent with fixed intermolecular chain-bonding of OH groups, and the lower from orientations of the OH groups as their bonding changes. Both the relative extent and the similar temperature dependences of the dispersions can be reasonably explained on this basis, as will be discussed in more detail elsewhere.

New Method of Direct Quantitative Inorganic Paper Chromatography

Several methods for the direct determination of substances separated by paper chromatography have been described. They are based, apart from mere visual comparison, either on measuring the area of the coloured spot[1] or determining its transmission by different methods[2].

In this laboratory a method has been developed which, in our opinion, is much faster and at least as accurate as any of those mentioned and which, so far as we know, has not yet been described in the literature. It is based on the determination of the reflectance of the coloured spot at the wave-length of minimum reflectance, a Beckman *DU* spectrophotometer with standard reflectance attachment being used and a paper blank serving as the 100 per cent reflectance standard. The only reference to reflectance measurements we have found is in the paper by Winslow and Liebhafsky[3], which measured the reflectance and transmittance in the case of ordinary spot tests. These authors, however, appear to assume that reflectance measurements should obey Beer's law, whereas in fact the Kubelka–Munk law[4] must be applied. Also their technique is of little practical value, as they stated themselves.

For reflectance measurements to be reproducible two conditions must be fulfilled. (*a*) A surface of constant area should be used for the measurements. This can easily be achieved by making the spots slightly larger than the circular opening in the mask or tab which covers the samples in the sample-holder of the reflectance attachment (in the case of the Beckman *DU* spectrophotometer this opening has a diameter of 1 in.; it can, of course, be made smaller by the use of suitable masks). (*b*) The colour must be uniform over the surface of the spot. This can be achieved in the paper chromatography of inorganic cations only if the initial solution has a high acidity, and if the R_F value is kept very low ($< 0·1$). We found that in this case it is possible to obtain spots of a very uniform colour, simply by letting the solution containing the cations spread through the paper. It is not even necessary always to use exactly the same volume of initial solution: in many cases the reflectance per unit area is independent, within certain limits, of the volume of the initial solution placed on the paper, and thus of the total area of the spot. This is a distinct advantage, as no accurately calibrated micropipettes are needed.

As an example, the procedure for determining nickel in the presence of other metals is here described. A series of standards containing 1–25 mgm. nickel in 100 ml. is prepared by dissolving a nickel salt in $3N$ hydrochloric acid. Similarly, a solution of the sample in $3N$ hydrochloric acid is prepared, the nickel content of which must fall in the same range. Small amounts of other acids do not appear to be harmful; but the final concentration should be very nearly $3N$. If nitric acid, for example, is needed for dissolving the sample, it should be eliminated by evaporation on the water-bath before making up the hydrochloric acid solution. About 0·045 ml. (containing 0·5–11 μgm. nickel) of the unknown and of the standards is spotted on Whatman No. 1 paper and allowed to dry at room temperature. The spots thus produced are slightly elliptical, having diameters of 30–33 mm. The dimension of the spot is not critical; volumes between 0·03 and 0·06 ml. may be used with identical results.

For chromatography, the ascending technique of Williams and Kirby[5] is used. The sheets of paper measuring 23 cm. × 23 cm. are fastened together (with white cotton thread) in the shape of cylinders. Each can accommodate six spots: one blank ($3N$ hydrochloric acid), three standards and two unknowns. They are placed in large jars containing acetone + 10 per cent $6N$ hydrochloric acid[6]. Development is preferably in the machine direction of the paper; after two hours it is complete. The sheets are dried for half an hour at room temperature, then half an hour at 60° C. Any residual acidity is neutralized by introducing them for a few seconds into a jar containing a dish filled with concentrated ammonia solution. They are then sprayed lightly (by means of an all-glass spray gun) with a 0·05 per cent solution of rubeanic acid in ethanol (94 per cent, carefully purified) containing 5 per cent (vol.) of concentrated ammonia solution. This solution is not stable and should be prepared immediately before use. Rubeanic acid gives coloured spots with iron, copper and cobalt, which have high R_F values. With nickel it produces a pure blue spot, which has moved only slightly ($R_F = 0·03$) and is thus completely separated from interfering metals.

On each spot a circle of 26 mm. diameter is drawn in such a way that its centre coincides with the approximate centre of the spot. The spots are then cut out and their reflectance measured at a wave-length of 625 mμ with a slit-width of 0·7 mm. Accurate centring under the tab of the reflectance attachment is made easier by the circle drawn on the spot. The standard of 100 per cent reflectance is a blank spot, for which pure $3N$ hydrochloric acid is used. The concentration of the unknown can then be read by interpolation, using a graph previously prepared from measurements on standard spots corresponding to solutions the nickel content of which increases by 1 mgm./100 ml. increments. This graph should only be used for facilitating interpolation, as the reflectance values for a given concentration vary slightly from one chromatogram to another. We found that accurate interpolation is always possible using three standards: 3 mgm., 10 mgm. and 20 mgm. nickel per 100 ml. and two unknowns of different concentration.

The precision of the method is very high. The coefficient of variation of a single measurement relative to the mean is 1·5 per cent for concentrations of 10–25 mgm. nickel per 100 ml. For concentrations down to 2 mgm. nickel per 100 ml. it is still about 3 per cent. The accuracy is equal to the precision if the amount of other cations is not more than ten times that of the nickel; for example, in a copper–nickel alloy (Belgian one franc coin) we found 24·55 per cent nickel, whereas chemical analysis gave 24·52 per cent nickel.

For alloys containing very low amounts of nickel, for example, ordinary steels, it is necessary to add to the developing solvent 4 per cent acetylacetone. In British Chemical Standard No. 239 (0·3 per cent carbon steel), which according to the certificate contains 0·23 per cent nickel, we found 0·21 per cent.

Full details of this investigation will be published elsewhere. Acknowledgment is made to Prof. E. Maes, head of the laboratory, for permission to publish this communication.

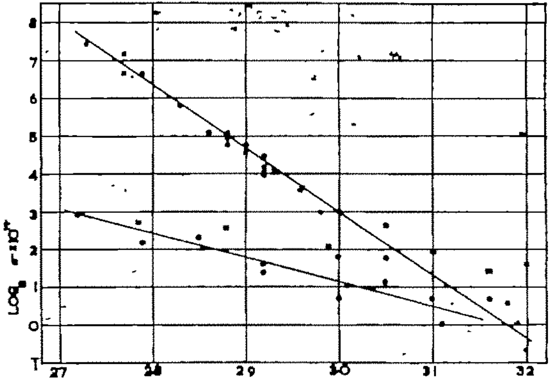
Effect of Temperature on the Conductivity induced in Insulators by X-Rays

DURING the course of an investigation into the conductivity induced in insulating materials by X-rays, it was observed that the conductivity of a length of polythene cable that had been irradiated six months before showed very marked dependence on temperature. In the case of similar cable unirradiated the effect was much less pronounced. Two samples of unirradiated cable were tested.

The previously irradiated cable had been subjected to a total of just under 5×10^5 r. given over the space of about a month at qualities of radiation ranging in value from 90 kV. H.V.L. = 1 mm. aluminium, equivalent wave-length 0·55 A.; to 230 kV. H.V.L. = 2·3 mm. copper, equivalent wave-length 0·10 A.

The cable, mounted as a flat spiral inside a metal box, was heated by a stream of hot air flowing around it. A potential difference was applied between the sheath and central conductor of the cable, and the current flowing through the insulation was measured by means of a high resistance and D.C. amplifier. The voltage gradient was 775 volts per cm. The temperature was raised in steps to the highest value, and reduced in similar fashion. It was maintained within ± 2° C. of any required value until the conductivity reached equilibrium value. Because of the smallness of the currents being measured, the accuracy was rather low at the lower temperatures.

The results are presented in the accompanying graph, showing an approximately straight-line relation between the logarithm of the conductivity and the reciprocal of the absolute temperature. Thus the equation $\sigma = \sigma_0 \exp(-W/kT)$ which holds for semi-conductors[1] appears to be applicable. From the slope of the graphs the value of W for the irradiated cable is found to be 1·45 eV., and for the unirradiated cable 0·50 eV.



Irradiated cable: ○, ascending temperature; □, descending temperature.
Unirradiated cable: ●, ascending temperature; ■, descending temperature

This suggests that conductivity in the latter may be due to electrons at a shallow level with respect to the conduction band, and in the former to positive holes produced by the radiation at a deeper level. If this is correct, then the contribution to the conductivity of the irradiated material made by the holes outweighs that due to impurity electrons as the temperature is raised.

It was pointed out by Farmer[2] that polystyrene shows a delay in returning to its original state after being irradiated. Polythene possesses a similar property, and it is a remarkable thing that six months after being disturbed, the mechanism of conductivity in the material had not returned to normal.

Note added in proof. The results obtained by Fowler and Farmer[3], for polythene cable both untreated and while undergoing irradiation, showed similar conductivity – temperature relationships to the above. They found much lower values of σ for unirradiated cable, and a value of $W = 1 \cdot 5$ eV. This is difficult to understand, as the specimens used were obtained from the same supplier. It appears that there must be some variation in the treatment of the polythene during manufacture. The higher conductivity could be associated with increased impurity content. The value of W for the cable undergoing irradiation was found to be 0·42 eV., and this is consistent with the supposition that radiation raises electrons from non-conduction levels to a level that is shallow with respect to the conduction band. Further measurements on various specimens of polythene are required to resolve the differences between the results.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN GEOGRAPHY (with good honours degree) at the Fourah Bay College, Sierra Leone—The Secretary, Advisory Committee on Colonial Colleges, 15 Victoria Street, London, S.W.1 (August 5).

LECTURER IN MATHEMATICS (with good honours degree in mathematics, and preferably with some teaching experience, and competent to teach pure and applied mathematics up to final degree standard)—The Clerk and Treasurer, Dundee Technical College, 40 Bell Street, Dundee (August 8)

RESEARCH ASSISTANT IN ZOOLOGY (graduate specially qualified in entomology and helminthology)—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (August 12).

LECTURER IN ELECTRICAL ENGINEERING (with honours degree in electrical engineering and industrial experience, and preferably some teaching experience)—The Secretary of University Court, The University, Glasgow (August 22).

PHYSICISTS, SENIOR EXPERIMENTAL OFFICERS (*a*) (with good knowledge of radiation measurements, and preferably with experience of industrial radiography) to take charge of group dealing with control of radioactive decontamination and radiation surveys, biological assays, personal dosage monitoring, etc., (*b*) (preferably with experience with remote handling devices) for research and development on radioactive materials (Ref. A.189/53A). EXPERIMENTAL OFFICERS and ASSISTANT EXPERIMENTAL OFFICERS (preferably with experience with high vacuum and metal evaporation techniques, construction and use of radiation measuring instruments, electron diffraction, high speed oscilloscopes for measurement of short time intervals) to assist in research and development work on radioactive materials (Ref. A.190/53A), at the Atomic Weapons Research Establishment, Aldermaston—The Ministry of Labour and National Service, Scientific and Technical Register (K), 26 King Street, London, S.W.1, quoting appropriate Ref. No. (August 22).

ASSISTANT LECTURERS IN CHEMISTRY (with qualifications in physical chemistry)—The Registrar, The University, Manchester 13 (August 31).

LECTURER IN GEOGRAPHY (with special qualifications and experience in mineralogy and petrology, or in palæontology, or in stratigraphy)—The Registrar, University College, Keele, Staffordshire (August 31)

SCIENTIFIC ASSISTANT, Deputy Chief Scientific Officer grade (with a veterinary qualification, and a broad general knowledge of the sciences involved, with extensive research experience in one of them), for agricultural research which is directed to the solution of problems arising from all aspects of animal health and husbandry—The Secretary, Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1 (August 31).

DEMONSTRATORS IN PHYSICS, CHEMISTRY AND GEOGRAPHY—The Registrar, University College, Keele, Staffs (September 1).

NATIONAL RESEARCH DEVELOPMENT CORPORATION SCHOLARSHIPS IN THE COMPUTING MACHINE LABORATORY—The Registrar, The University, Manchester 13 (September 1)

RESEARCH FELLOWSHIP IN SCIENCE at the University of Durham—The Secretary, 38 North Bailey, Durham (September 1).

RESEARCH STUDENTSHIPS IN GEOGRAPHY, PSYCHOLOGY, MATHEMATICS, PHYSICS, CHEMISTRY, BIOLOGY and GEOLOGY—The Registrar, University College, Keele, Staffs (September 1).

SENIOR EXPERIMENTAL OFFICER (with degree in a scientific or engineering subject, or a Higher National Certificate, or a graduate membership of a professional institution) AT THE FOREST PRODUCTS RESEARCH LABORATORY, Princes Risborough, Bucks, for research work and liaison with industry at high technical level on the uses of new timbers and their value as substitutes for traditional ones now unobtainable—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4234/53 (September 3).

ASSISTANT LECTURER IN MATHEMATICS (preferably with special interest in some branch of applied mathematics) in the Manchester Municipal College of Technology (Faculty of Technology in the University of Manchester)—The Registrar, College of Technology, Manchester 1 (September 7).

READER IN GEOGRAPHY in the Durham Division of the University of Durham—The Registrar, University Office, 46 North Bailey, Durham (September 10)

PROFESSOR OF GEOLOGY at the Victoria University College, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 1).

LECTURER IN BACTERIOLOGY at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 2).

ENGINEER, PHYSICIST or MATHEMATICIAN (with first- or second-class honours degree or equivalent qualification in engineering, physics or mathematics, and at least three years relevant postgraduate research experience) in the Ministry of Supply Research Branch, Tolworth, Surbiton, to work in small team engaged in design and development of wide range of survey, photographic and printing equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.194/53A.

PHYSICIST or RESEARCH ENGINEER (with first- or second-class honours degree, and research experience, preferably in textiles, plastics or similar materials) to carry out basic research on the mechanical properties of fabrics—The Director of Research, The British Cotton Industry Research Association, Shirley Institute, Didsbury, Manchester 20.

PROFESSOR OF CIVIL ENGINEERING at the Israel Institute of Technology, Haifa—The Secretary, The Technion Society of Great Britain, 13 Mansfield Street, London, W.1.

PROFESSOR, and an ASSISTANT PROFESSOR, IN THE DEPARTMENT OF PHYSICS—The Dean, A. A. Duri, College of Arts and Science, Baghdad, Iraq.

Progress
+ Purity
= Glass

No other material gives you quite the same advantages as glass for large-scale industrial production of foodstuffs, chemicals and drugs. You obtain laboratory standards of purity, simplicity of control and perfect cleanliness without risk of corrosion. The extent to which glass is being used in large modern industrial plant is evidence of its efficiency and its adaptability. If you have any doubts about the efficiency or adaptability of glass, please do get into touch with us. Our experts are ready to explain, advise or be constructive about any problem in connection with the use of glass in industrial production.

See the job through

You take any amount of time and trouble to ensure that oscillograph records like this are accurate and reliable. But no matter how careful you are, what sensitized materials you use or how efficient your apparatus, the quality of the finished record depends to a large extent on the quality of the photographic chemicals you use.

That makes it important to process all your materials with 'Kodak' Chemicals. They have been tested both in the laboratory and the darkroom . . . . . they are balanced for exact uniformity from batch to batch . . . . . they are accurately compounded and only require the addition of a specified amount of water to make them ready for use.

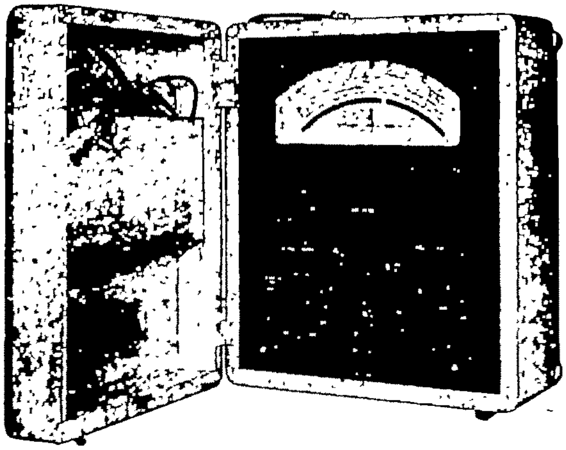
Instruments for Research & Industry



MODEL 44

Substandard

Multi-Range Meter

An outstanding instrument for general laboratory use and for calibrating single or multi-range meters. The 44 ranges cover from 1 mA. to 10 A. and 1 V. to 1,000 V. on D.C. or A.C. The accuracy on all D.C. ranges is SUBSTANDARD and on all A.C. ranges is considerably better than First Grade. These meters are made with the greatest care and have been supplied for many years to leading laboratories at home and abroad.

THE DEFENCE OF INTELLECTUAL FREEDOM

THE extent to which freedom is a vital issue to-day is illustrated by the discussion in Britain provoked by the publication of the White Paper on the Political Activities of Civil Servants, and more especially by the effect of secrecy requirements on the publication of research in nuclear physics. It is reflected in the discussion as to the position of the private foundation or voluntary organization in the endowment of scientific research, which has arisen in recent years on the reports of the Nuffield Foundation, the Rockefeller Foundation, the Carnegie Trust and Lord Beveridge's study of "Voluntary Action". It is to be seen, too, in the interest which has been taken in the loyalty inquiries in the United States, among both the employees of that Government and among the employees of the United Nations. Scientists indeed have been particularly interested in some of the results of what is popularly termed 'McCarthyism' or 'witch-hunting', and have welcomed the dignified and firm defence of academic freedom which individuals and universities have made.

That defence led last March to the issue by the Association of American Universities of a statement on "The Rights and Responsibilities of Universities and their Faculties" (obtainable from the Department of Public Relations, Princeton University, Princeton, N.J.). The statement was adopted unanimously by the heads of thirty-five of the leading universities in the United States, and its forthright championing of the free mind and free inquiry, and of the right and duty of candour and freedom of speech, is far from being the platitudinous verbiage it might have seemed a generation or two ago. While it is pointed out that academic freedom never implies freedom from criticism, firm protest is made against the application of special loyalty tests to university faculties. Such discrimination harms the individual—and even more the university—and the whole course of education by destroying faith in the ideals of university scholarship.

When the powers of legislative inquiry are abused, however, the remedy is not to be sought in non-co-operation or defiance: the Association concludes that it is to be sought through the normal channels of informed public opinion. This conclusion, moreover, is of interest in another connexion which is deeply perturbing most American scientists and technologists, and which is being followed with close interest by their colleagues in Britain. The sudden dismissal of Dr. Allen V. Astin from his post as director of the National Bureau of Standards raised doubts as to whether or not high technical positions in the Government service would be subjected to political pressure whenever there was a change of administration. As a result of the storm raised in the Bureau of Standards itself, in the scientific press and elsewhere, Dr. Astin has now been temporarily reinstated; but the reflexions on the professional integrity of the Bureau and on Dr. Astin's own integrity and competence do not appear to have been withdrawn, although in the meantime the

Massachusetts Institute of Technology has reported in exactly the same terms as the Bureau in its circular on battery additives which the United States Secretary of Commerce ordered to be withdrawn.

It seems unlikely in the circumstances that any outstanding scientist whose attainments command national respect will accept the position of director in succession to Dr. Astin, and American scientists are concerned that the dissatisfaction in the Bureau of Standards is likely to spread to other government agencies in the United States employing scientists. They argue that if any government agency should be immune from outside pressure of any kind it is the Bureau of Standards, which is the leading adviser on scientific matters to industry as well as to government agencies. The institution in Great Britain which most resembles the Bureau is the National Physical Laboratory, and British scientists will readily appreciate the argument that an institution concerned with testing and evaluating for the Government thousands of products and processes cannot function properly if it is subject to political or other influence.

Whether or not it is too much to maintain that scientific research is bound to suffer from any departure from the Bureau's established policy of rendering an impartial judgment on any matter with which it is confronted, the episode illustrates that professional freedom and integrity are of practical and not merely theoretical interest to-day. That much was, of course, brought out in Prof. A. Macbeath's "Plea for Heretics" at the British Association meeting in Belfast last September, and such considerations have prompted the publication during the past two or three years of such books as Prof. Gellhorn's "Security, Loyalty and Science", Mr. Barth's "The Loyalty of Free Men" and the anthology entitled "Primer of Intellectual Freedom". These, however, are only a few of the recent contributions to the discussion, and they have already been referred to in these columns. Two other sharply contrasting books may be mentioned here; they make no attempt to examine the present situation or the policies now being pursued by governments, universities, professional bodies and democratic institutions; but they are of special interest for the light they throw on the principles and practices which may arise out of the present situation.

The first of these books, J. M. Brewer's "Wellsprings of Democracy"*, is severely practical or pragmatic. Its approach is not theoretical or philosophical, as its title might seem to suggest, but is indicated rather in the sub-title, "Guidance for Local Societies". It is concerned with procedure, with the way in which democratic associations, of any kind or on any level, work, the demands they make on their members, and the conditions for successful functioning, whether in a business organization, a works council or board meeting, a scientific or a local society. It is intended to assist people to participate in the business of such a democratic organization and also to make them aware of the pitfalls and the dangers which hinder co-operation and which, if unchecked, may transform a democratic association into an autocratic or moribund one. Save in one chapter, however, the philosophical aspect is never touched and, though strictly practical, the book makes dry reading and lacks the vision and vitality of books like Sir Ernest Barker's "Reflections on Government" or Lord Lindsay's "The Modern Democratic State" or his lectures on "Religion, Science and Society in the Modern World".

Mr. Cranston's book* is of the opposite type. This new analysis of freedom is concerned with the theory rather than the practice of freedom. It begins with a brilliant analysis of the meaning of freedom which clearly and forcefully dispels the ambiguities in the use of the word and the fallacious reasonings frequently based on these ambiguities. In this part alone the book makes an outstanding contribution to current discussions on freedom, and should prevent them from becoming as sterile and impractical as they often are. Ambiguity, he insists, is only avoided if, like the late President Roosevelt, we define freedom as freedom from or freedom for some specific purpose or object.

This really excellent essay on precision in the use of words deflates the frequent pretentiousness of metaphysicians and obscurantists as well as of politicians; but it equally exposes the real difficulties and incoherences in the thought and tradition of liberalism, both in the academic and the political fields. The ambiguity of liberalism is examined more fully in the second part, the successive chapters of which deal with liberalism as it is understood in Great Britain, in France, in Germany and in the United States. Here again is a most useful contribution to clear thinking and a solvent of misunderstandings when, for example, British and American scientists are discussing such matters as the defence of professional or academic freedom in the context of the particular society of which they are members.

When we come to the third part, however, Mr. Cranston turns determinedly into the philosophical field and examines the eternal problem of determinism and free will. Here his lucidity of exposition does not forsake him, and he can still be read with ease and pleasure by the lay reader; but this part is not so clearly related to what has gone before, nor is it of the same interest and relevance for the great practical debate of our times. The great value of the book lies rather in the insistence that the word 'freedom' is not completely descriptive, and its warning against dangers inherent in the emotive meanings or connotations of laudatory words of this kind—a warning to be heeded by the scientific writer, whether he is dealing with some aspect of freedom as it affects science, or with some aspect of science as it may affect technology or society. Without disparaging the third part of the book as a philosophical disquisition—though Mr. Cranston's verdict against determinism and in favour of the libertarian analysis of the freedom of will includes reservations—it disappoints the reader who may well have been led by the excellence of the first two parts to expect an equally lucid exposition of the nature of the free society and the conditions on which such a society can exist.

---

* Wellsprings of Democracy: Guidance for Local Societies. By John M. Brewer. Pp. xii+232. (New York: Philosophical Library, Inc., 1952.) 4.50 dollars.

* Freedom: a New Analysis. By Maurice Cranston. Pp. viii+177. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1953.) 12s. 6d. net.

Such an exposition Mr. Cranston could undoubtedly give us, and his indication of the contribution which the philosopher could make to clear thinking and constructive debate induces the hope that he may still attempt it. He has shown us plainly that, without clear ideas of the meaning of freedom, confusion and misunderstanding are inevitable and to that extent stimulate the careful examination which should form the basis for any firm defence of academic freedom and opposition to the invasion of civil rights, both in the Civil Service and in technical fields like that of atomic energy. But on the issue of responsibility and the choice of freedom, Mr. Cranston says little, though his clarity of thought and his avoidance of jargon suggest that he could write much that would help the layman as well as the professional philosopher.

"Parliamentary institutions, with their free speech and respect for the rights of minorities, and the inspiration of a broad tolerance in thought and its expression—all this we conceive," said Her Majesty the Queen, in her Coronation Day broadcast, "to be a precious part of our way of life and outlook." If all this is to be cherished and practised, much more is required than the formulation and observance of the appropriate rules and organizations with which Mr. Brewer's book is concerned. We must have clear understanding of what we mean by freedom in the political and social context of our time, and of the conditions under which those freedoms which we wish to cherish are best nourished. Our defence of intellectual freedom—the right of investigation and of communication in whatever aspect—can only be securely based on a like clear understanding of the whole situation, and its philosophical, no less than its practical, implications.

FROEBEL'S INFLUENCE ON ENGLISH EDUCATION

Friedrich Froebel and English Education

By P. Woodham-Smith, J. P. Slight, O. B. Priestman, H. A. Hamilton, N. Isaacs. Edited by Evelyn Lawrence. Pp. 248+12 plates. (London: University of London Press, Ltd., 1952.) 20*s*. net.

THE purpose of this book, to make a faithful record of the development of Froebel's educational concepts in relation to English education over the past century, is carried out with admirable objectivity. As the story unfolds, it is brought home to us that much which we tend to think of as specifically the pressing problem of our times is inherent in progressive education at all times.

The expansion of Froebel's ideas is traced through chance factors of ideas, social problems and, above all, the type of disciple he inspired. Froebel's own ardent mind, always seeking hidden connexions, underestimating his powers of suggestion, impatiently generalizing from insufficient data and imploring educationists to show greater respect for childhood, fired the imagination of the singularly fine quality of women who were struggling for emancipation all over the world; the German Baroness von Marenholtz, the Indian Pundita Ramabai, the headmistresses of such outstanding schools as Notting Hill and Croydon High Schools and the North London Collegiate, the stepdaughter of the first Mistress of Girton and many others incorporated the idea of the emancipation of children in their own campaign. Outstanding men, such as Dickens, gave the idea critical and appreciative attention. Froebel's enthusiasm had first been roused by the international group of young men he met in Pestalozzi's school, and the international appeal of the ideas resulted in kindergartens opening in countries far beyond Europe; moreover, contact was maintained between the work in different countries—for example, the British interest in the American developments under Dewey.

The story is told of Froebel's pioneering, how he saw play as an activity as purposeful as work and revolutionized the child–adult relationship, supplanting repression with encouragement and making fellow teachers and learners of both. His reason for concentrating on the very young was merely that he saw this age, denied the sacred right of discovery, as the weakest link in the vital chain of development. He begged for no slavish following of his suggestions and, in order to minimize this, had to attend to the training of educators. The story is told of the ceaseless fight for training teachers in freedom, in order to preclude misuse of practice through misconception of principles, and how this led to a much finer quality of teacher for the very young than had previously been thought necessary. Although certain restrictions in government schools meant that the kindergartens had to be privately run, the spiritual basis of the work and the sense of vocation in the training convinced the Froebel teachers that their ideas concerned all children, and the story is laced with accounts of out-of-school activities and club work. Societies had to be formed to maintain standards, encourage pioneering and prepare public opinion.

The chapter on Froebel's religious philosophy is tackled on too narrow a field, since it fails to throw light on the international inter-religious appeal of his spiritual concepts. It is generally accepted that he was an unsystematic philosopher and that he, like some of the earlier psychoanalysts, mistakenly believed childhood tensions could be entirely eliminated; but there is grandeur in this misconception when we realize that it was arrived at through surmounting the most terrible tensions in his own childhood, and we have far to go before we have eliminated unnecessary suffering in children.

The final chapter is one of the finest expositions yet written of the principles underlying modern educational practice. The style is clear and temperate, and the survey, though brief, is very extensive. Froebel's principles are formulated systematically, and attention is directed to recent results from studying children, which are related to our changed picture of the world. In conclusion, there is a thought-provoking study of the nature of unresolved clashes in ultimate philosophies and a new approach to the problem of freedom of thought which virtually compels us to take on the responsibility of granting children their right to be prepared for the responsibility of freedom. If we act quickly, we may still be in time to save the human race by emancipating the children. P. M. PICKARD

"FLYING SAUCERS"

Flying Saucers

By Prof. Donald H. Menzel. Pp. xii+319. (London: Putnam and Co., Ltd., 1953.) 21*s.* net.

THERE is a deep-rooted human instinct to regard as supernatural anything the cause of which is not immediately obvious, especially phenomena in the heavens. In early days there were the gods, either manifesting their anger in the thunderbolt or warning humanity of impending tragedy by comets or other portents. As successive phenomena received natural explanations, the supernatural began to give place to the superscientific, and in place of gods we have visitors from other worlds. Prominent among these are the 'flying saucers'—space ships of a mysterious race called 'saucerians'.

The story of 'flying saucers' begins on June 24, 1947, when a business man on a private flight in Washington State saw "a chain of saucer-like things at least five miles long, swerving in and out of the high mountain peaks. They were flat like a piepan and so shiny they reflected the sun like a mirror. I never saw anything so fast". Publication of this story in the Press was quickly followed by other reports, and when the U.S. Air Force began an official investigation, the great American public-soon joined in. Saucers were seen on every hand, by day and night, from the ground and the air, at all levels and even landing. Between 1947 and July 1952, no fewer than 1,157 'saucers' were recorded. It was high time that a level-headed scientist investigated, and Prof. D. H. Menzel, professor of astrophysics at Harvard, was well qualified for a one-man jury. His book, though not very systematic, is thorough, and he adjudicates on a large number of reports, in many cases after personal interview with the witness.

Many of the descriptions are so disguised by hasty examination, preconceptions, or subsequent exaggeration that it is hard to say what was actually seen; but on the whole, 'flying saucers' may be classified into three groups: real but natural phenomena, man-made objects, and hoaxes. The natural phenomena include a wide variety: stars and planets; will-o'-the-wisps; electrical phenomena such as auroræ, St. Elmo's fire and possibly the little-understood ball lightning; sun dogs, mock suns and mock moons and other phenomena due mainly to ice crystals; peculiar cloud formations; and 'Foo fighters' or small whirls of ice crystals formed by the wings of a plane—one pilot reported a fight with one! The author thinks that many saucers, especially those seen from moving cars and seeming to skim the earth's surface, are simply mirages of distant peaks, and he devotes a long appendix to the theory of mirages.

Among man-made 'flying saucers' there are almost certainly weather balloons, but also such things as searchlight rings on cloud, which of course move about with incredible speed when the beam shifts. Then there are the 'galloping ghosts' of radar, due simply to the mechanics of that form of super-vision.

Finally, hoaxes. In 1938 a radio adaptation of H. G. Wells's "War of the Worlds" was taken as truth by at least a million listeners, some of whom actually saw the battle or smelt the smoke. That matter was soon cleared up; but the "little men from Venus" who, as described by a lecturer at the University of Denver, actually came out of a saucer, are not quite dead yet.

Although there remain a few reports which cannot be fitted into any known category, the author is firmly of the opinion—with which most thinking people will agree—that whatever they were, they were not visitors from the stars, and he supports this with a brief survey of the conditions which render civilized life, on the planets at least, highly improbable. 'Flying saucers', under other names, have been always with us, as angels and heavenly hosts, which survived even to the 'angels of Mons', and later, when the possibility of directed flight first arose, as wonderful airships (that is, lenticular clouds). It is unlikely that readers of *Nature* have ever believed in flying saucers as interplanetary visitors; but they will find this book well worth study for its store of information about curious natural phenomena, as well as for its entertainment value.

C. E. P. BROOKS

"THE MERCK INDEX"

The Merck Index of Chemicals and Drugs

An Encyclopedia for the Chemist, Pharmacist, Physician and Allied Professions. Sixth edition. Pp. xiv+1167. (Rahway, N.J.: Merck and Company, Inc., 1952.) 7.50 dollars; thumb-indexed, 8 dollars.

THIS attractive compendium will be familiar to many chemists, pharmacists and medical men through its earlier editions. First published in 1889, it has undergone a series of metamorphoses and modernizations. The fifth edition was published in 1940. The present edition is already assured of a wide circulation, for nearly fifty thousand copies are said to have been ordered prior to publication. There are more than eight thousand descriptions of individual substances, more than two thousand structural formulæ, drawn to conform to the Ring Index, and about twenty thousand names of chemicals and drugs—these include many trade names with their equivalents. Although primarily intended as a work for rapid reference, browsing in the new "Merck Index" is a fascinating and stimulating exercise.

Appendixes occupy some hundred and forty pages and include a list of more than three hundred 'name' reactions with descriptions and references; a table of radioactive isotopes with their half-life periods, types of radiations and medical uses; and a list of dyes permitted in the United States for colouring foods, drugs and cosmetics.

The choice of compounds selected for inclusion in the "Index" seems somewhat arbitrary. There is a wide range of natural and synthetic drugs, and for these chemical descriptions are given, with literature references to their determinations of structure and methods of synthesis. Toxicities and medical and veterinary uses are briefly indicated. Many natural products having no established therapeutic applications are also included, together with a variety of purely synthetic products having no connexion with medical usage. These last probably represent a survival of the design of the first edition, which included in its title "a summary of whatever chemical products are to-day adjudged as being useful in either medicine or technology". Non-medicinal substances not of natural occurrence described in the "Index" include the monochloronaphthalenes, Cleve's acids, decalin and tetralin, and polycyclic aromatic hydrocarbons such as chrysene, picene, pyrene and 3 : 4-benzpyrene. Entries relating to an interesting series of siloxanes are also dispersed through the pages. In some cases the reason for inclusion is not apparent. Thus, there is a relatively lengthy entry relating to the synthesis and properties of 9 : 10-dimethyl-1 : 2-benzanthracene, but without any reference to its high carcinogenic activity, which is the main reason for interest in this compound.

Not all the entries are completely up to date, and when a seventh edition is prepared the opportunity should be taken to correct a few errors and repair omissions. For example, the tentative structure attributed to β-erythroidine has now been superseded. The structures given for caryophyllene and solasodine are out of date and have been corrected by recent work. The functional substituents of the tropolone ring of colchicine are incorrectly placed. The latest reference given for corynanthine is dated 1911. There should be mention of more recent work, and especially of the structural relationship of corynanthine to yohimbine. Again, allusion should be made to recent work on the structure of rubijervine, the latest reference to which is dated 1890. Out-of-date structures are also assigned to puberulic and puberulonic acids, and there is no mention of the other natural tropolones, except colchicine. These examples, selected at random, serve to emphasize how difficult it is to keep abreast of modern developments in such a wide field as is covered by the "Merck Index". J. W. Cook

THE LONDON MINT

The Mint

A History of the London Mint from A.D. 287 to 1948. By Sir John Craig. Pp. xviii+450+16 plates. (Cambridge : At the University Press, 1953.) 70s. net.

The author, a former deputy-master and comptroller of the Royal Mint and engraver of the King's Seals, to give him his full titles, is already well known by his fascinating little study "Newton at the Mint". The present work is a more substantial piece of historical research, for which Sir John Craig has pre-eminent qualifications. Minting has been carried out in London, in any event since the time of the Roman occupation, and the account now presented extends from then to the present time. To the historian, to the economist, to the numismatist and to the technologist, this account of the activities of the Mint during these seventeen hundred or so years is of first-rate importance.

The ground covered is very wide, and it is difficult to believe that any significant aspect of the Mint's activities has been overlooked. The holiday-maker, for example, chafing under restrictions in the amount of English currency which he may take abroad with him, can take comfort in the fact that "it was almost always unlawful from the Statute of Stepney in 1299 to take coin or precious metal out of the country without licence". The production of such coin in medieval times in a very large number of mints distributed over the whole country was gradually concentrated in London, until, in 1553, the Tower Mint became the sole source of the English coinage. Only at times such as the Civil War, when many local mints were opened to provide for the payment of troops, and during periods of intense recoinage, such as that for which Newton was responsible, were the activities of the London Mint decentralized. The difficulties under which the coinage was produced led at times to acute shortages, and even as late as the third quarter of the eighteenth century foreign coin came into Britain and circulated without let or hindrance on its bullion value. The control of the purity and weight of our coins is determined by the Trial of the Pyx, an assay which must have been instituted not later than about the middle of the thirteenth century. The practice has changed since then on many occasions, and is here described with what might almost be called affectionate care.

There is much in the treatment of immediate interest to the economic historian; particularly is this true of the output of gold and silver coin, recorded in an appendix almost year by year from A.D. 1273 in the case of silver and 1344 in that of gold.

The utilization of the best scientific minds of the day has been evident since the time of Newton himself. In one way or another Cavendish, Boulton, Watt, Graham, Roberts-Austen and Herschel, among many others, have directed or assisted the London Mint.

This outstanding piece of historical research is presented to the ordinary reader free from any suspicion of heaviness, well illustrated by plates of coins, machines, maps, medals and portraits, and admirably indexed. It represents a most important contribution to English history. F. C. Thompson

FIELD TRIALS WITH PERENNIAL PLANTS

Field Experimentation with Fruit Trees and other Perennial Plants

By S. C. Pearce. (Commonwealth Bureau of Horticulture and Plantation Crops, Technical Communication No. 23.) Pp. x+131. (Farnham Royal : Commonwealth Agricultural Bureaux, 1953.) 10s.

The application of modern statistical methods to experimentation in a particular field of research frequently introduces new problems, and these in turn lead to new ideas and developments which are very often of interest to experimenters in general. For this reason the appearance of a specialized study such as that under review is usually welcome. Dr. Pearce's book presents an account of the design, practice and analysis of experiments with perennial crops. It has been written by a statistician who has had considerable experience of these subjects at East Malling Research Station.

After a brief introductory chapter, a number of experimental designs are described in Chapters 2 and 3. Most of these designs are in general use. Their main purpose is the control of positional variation. Interesting new material is provided in the sections on designs which allow thinning out of plants during the course of an experiment, and designs which allow further experiments to be carried out on the same plantations. Methods for controlling non-positional variation, which is frequently of great importance with perennial crops, are discussed in Chapter 4. The next chapter contains useful practical recommendations on the size and shape of plots, the use of guard rows, and the provision of adequate replication. A discussion of the types of design appropriate to different subjects of investigation follows.

The remainder of the book is concerned with the measurement of observations and the analysis of results. The arrangement is rather unusual in that computational details are relegated to four appendixes, where they are given in general terms. Whether readers will be able to grasp the principles underlying the least-squares methods of estimation and the analysis of variance and covariance from these appendixes remains to be seen. In Appendix 3 the method for determining variances and covariances is unnecessarily laborious, while Appendix 4 is restricted to only one particular use of the analysis of covariance, although this is not stated. The main text includes discussions of the interpretation of results, the use of transformations and the treatment of incomplete data. The final chapter is an account of the methods of measurement of perennial plants adopted at East Malling. An extensive list of references and a subject index are given at the end of the book.

Dr. Pearce has addressed his book to experimenters already possessing an elementary knowledge of statistical technique, thus leaving himself free to discuss the many points which his experience has suggested are of practical importance. Many interesting issues are raised and discussed at length; but others, particularly some of those which must arise with the development of the science, receive little attention. Thus there appears, at least to the reviewer, to be an undue emphasis on 'significant differences' which, as the discussion in Section 72 shows, are troublesome things, often more confusing than helpful. Perhaps the most disappointing feature of the book is the dismissal in little more than a page of the many problems connected with the analysis of the results of an experiment lasting several years, while the only real long-term design considered (Section 60) is full of pitfalls for the inexperienced or uncritical reader.

Sometimes the expression is rather loose. The statement on p. 55, relating to amounts of fertilizers, that "with a perennial the optimum application is changing all the time as the trees become older so there is no point in trying to determine what it is" can scarcely have been meant. Again, Section 92 contains some very curious comments on sampling methods and a formula which in its present unqualified form is obviously incorrect. Nevertheless, the book contains a great deal that should be of value to the experimenters for whom it is intended.

H. D. Patterson

PROGRESS IN NUCLEAR SCIENCE

Annual Review of Nuclear Science

Vol. 2. Edited by James G. Beckerley. Pp. x+429. (Stanford, Calif.: Annual Reviews, Inc.; London: H. K. Lewis and Co., Ltd., 1953.) 6 dollars.

THE second volume of this series is considerably more compact and homogeneous than its predecessor. For one thing, the subjects of the reviews are limited entirely to one aspect of nuclear science (physics); for another, many of the essays are not just miscellaneous collections of details of recent work, but present a clear and comprehensive picture of their subject as a whole. To a considerable extent, of course, this is dictated by the nature of the subject. Thus, the article on accelerators (Chu and Schiff) is all that one can expect it to be: a brief and interesting survey of recent developments on various machines and types of machine. Similarly, the essay on isotopes (Bigeleisen) gives fragments of information ranging from mass measurements to isotope effects in chemical kinetics. There is a certain amount of overlapping in the articles on "Nuclear Reactions induced by High Energy Particles" (Templeton) and "High Energy Fission" (Spence and Ford). "Radiation Effects in Solids" (Dienes) include a variety of electrical and mechanical properties, notably the transformation of *n*- to *p*-type germanium. The essay on "Nuclear Moments" (Feld) is concerned with the determination of moments of unstable nuclear states; and with a comparison between experiment and theory of the moments of stable states, particularly as predicted by the independent particle model. "Recent Studies in Photonuclear Reactions" (Strauch) discusses the significance of the peak which occurs in many photonuclear reactions between 10 and 20 MeV. "Subnuclear Particles" (Blair and Chew) is a condensed and useful summary, especially of the properties of pions and their interaction with nucleons. In "β-Decay Energetics", Coryell studies the applicability of the empirical nuclear mass formula to β-decay: and in "Nucleon–Nucleon Scattering", Breit and Gluckstern are concerned chiefly with the evidence for, and the explanation of, high-energy differential p—p scattering, with its constancy with angle and energy over a wide range. The essay on "Natural Radiocarbon" (Anderson) is an interesting discussion of the close agreement between the observed specific activity and the estimated production-rate from cosmic rays.

The remaining articles are rather more comprehensive in their scope. In the "Origin and Abundance of the Elements", Alpher and Herman survey the evidence for the cosmic abundance of the elements, and emphasize the close correlation between the abundance of an element and its fast-neutron capture cross-section. Various theories of the origin of the elements are presented, with emphasis on the neutron-capture theory. The article on "Angular Correlation in Nuclear Radiation" (Frauenfelder) is a concise and detailed account which makes clear the part played by the field of the electron shell (both stable, as in an ionic crystal, and unstable, as in the atomic shell during decay) in perturbing the angular correlation. The "Theory of β-Decay" (Konopinski and Langer) discusses the various interactions of the Fermi theory, and their occurrence in allowed, favoured and forbidden transitions. The "Origin of Cosmic Rays" (Biermann) is an interesting study which lays emphasis on occasional but marked bursts of cosmic radiation, such as that of November 19, 1949: the times and places of arrival, compared with the accompanying solar flare, suggest solar origin, but considerable deflexion, probably by magnetic fields, in the neighbourhood of the solar system. Theory suggests that these interstellar fields are of the order of 10^{-6} gauss and that they play a major part in the storage and acceleration of cosmic rays. Finally, there is an exceptionally clear article by Salpeter on the "Energy Production in Stars", which presents a succinct summary of the basic astrophysical data and of the methods of calculating temperature and density distribution in stars. The nature of the P—P cycle, and the experimental evidence for the carbon–nitrogen cycle, are discussed: from this, a theory can be built up which accounts reasonably well for the energy production in main sequence stars. To the reviewer, this was the most interesting essay of a good collection.

W. D. Allen

Ultraviolet Spectra of Aromatic Compounds

By Dr. Robert A. Friedel and Dr. Milton Orchin. Pp. 52+579 Spectra. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1951.) 80*s.* net.

AFTER so many publications on the theory of aromatic character, a book dealing with purely experimental data is refreshing. This work contains a collection of 579 absorption spectra, all on the same scale (one inch corresponds to 400 A. and also to one unit on the log ε scale). The loose-leaf binding allows the pages to be removed so that spectra may be compared directly. Unfortunately, the curves are not supplied with the values for the maxima, which the user must estimate by measurement of the graphs.

The collection of ultra-violet absorption curves is preceded by a short theoretical introduction of thirty-six pages. A brief account of the experimental procedure is given with reference to the American-manufactured Beckman and Cary recording spectrophotometer; the use and influence of solvents are described. The theoretical section is concerned only with classical theories and useful empirical rules. The effect of introduction of various substituents (alkyl, alkenyl, aryl, hydroxyl, amino, methoxyl, carbonyl, cyano, nitro and halogen), the effect of steric hindrance, the fine structure effect, etc., are clearly described and explained, using predominantly examples taken from the American literature. Other chapters deal with the use of absorption spectra for qualitative and quantitative analysis. All this is expertly and succinctly done.

The formula of each compound, its name, the solvent used, and the literature citations are given alongside each absorption curve. The references do not always give the name of the author who first described the quantitative spectrum of the pure compound, but relate to the most recent reproduction of the absorption curve. It would have increased the value of the work if the bibliographies had been more complete.

This well-printed collection of absorption spectra will undoubtedly attract widespread interest, and it is to be hoped that it will be followed without much delay by an improved new edition.

E. Clar

Progress in Metal Physics

(Progress Series.) Vol. 4. Editor: Dr. Bruce Chalmers. Pp. viii+408. (London: Pergamon Press, Ltd., 1953.) 60*s.*

IN recent years the output of research work in metal physics has been so great that few have been able to keep in active touch with more than a small proportion of the subjects which are now advancing so rapidly. The original purpose of the present series of books was to present authoritative reviews written with the direct object of enabling "research workers in one part of the field to remain up-to-date in other branches" (foreword to Vol. 1 reprinted in the present book). Unfortunately, those responsible for the series appear to have lost sight of its original purpose, and the present volume will be of little value to those wishing for reports enabling them to realize easily the progress made in branches of science other than their own. For this purpose the seven articles in the book are nearly all too long, and are written in such a way that only occasionally can the real progress be seen unobscured by a mass of secondary detail. The book must therefore be regarded as one which fails in the original purpose of the series; but at the same time it will be of great value to those who are so directly concerned with the subjects reviewed that they are willing to consider papers the length of which varies from 30 to 66 pages, with from 80 to 191 references. For serious study of this kind the book can be recommended; the articles are authoritative and good, except that the standard of writing is variable, and sometimes becomes little more than a collection of references or brief extracts.

The subjects dealt with are: (1) internal friction in metals (A. S. Nowick); (2) the mechanism of oxidation of metals and alloys at high temperatures (K. Hauffe); (3) gases in metals (C. R. Cupp); (4) the theory of sintering (G. A. Geach); (5) theory of dislocations (A. H. Cottrell); (6) diffusion in metals (A. le Claire); (7) nucleation (J. H. Hollomon and D. Turnbull).

W. Hume-Rothery

A Contribution to the Theory of the Living Organism

By Prof. W. E. Agar. Second edition, revised. Pp. vi+235. (Melbourne: Melbourne University Press; London: Cambridge University Press, 1951.) 27*s.* 6*d.* net.

IN this, the second edition, Prof. W. E. Agar has maintained and elaborated his thesis of living organisms—and he means all organisms—as perceiving, experiencing subjects, capable of purposive actions, in an effort to attain limited 'hormic goals', which, however, may have very important biological consequences. With some rearrangement of his materials, the emphasis, as before, is on the essential unity of the organism, on the possibility of considering it, on grounds which are strictly scientific, as a psychophysical system, and on behaviour in terms of perception. It is evident that the author has been at great pains to state his ideas, reasons and conclusions with precision and clarity, his concluding chapter on evolution being a model of its kind. This is a work which will be read with appreciation by those who are specially interested in the philosophy of biology; but it deserves to be introduced to a much wider circle.

Science News, 25

Edited by A. W. Haslett. Pp. 128+24 plates. (Harmondsworth: Penguin Books, Ltd., 1952.) 2*s.*

THE twenty-fifth number of "Science News" maintains the standard set by the former volumes. An important article by N. W. Pirie entitled "Concepts Out of Context" examines the concepts of species, purity and efficiency and shows how fundamental errors can occur by the transference of a concept into a field in which it is inapplicable. "A sensible philosophy controlled by a relevant set of concepts saves so much research time that it can nearly act as a substitute for genius. . . . We avoid the problems which are real in adjacent fields but are pseudo in our own." There follows a good summary by J. Little of the use of radio-frequency methods in the study of atoms and molecules. D. E. Tribe writes briefly on the validity and significance of self-selection of diet in animals; and J. E. Sutcliffe on the mechanism of mineral salts absorption by plants. A more extended essay by Katharine Tansley and R. A. Weale reviews the evidence against the trichromatic theory of colour vision. Current lines of research and development in gas turbines are reviewed by J. Hodge. There is an account of progress in underwater television with interesting photographs, an article by Margaret Knight on consciousness of the brain, and a research report.

W. L. Sumner

SOME RECENT DEVELOPMENTS IN THE USE OF AIRCRAFT AGAINST FLYING LOCUST SWARMS

By DR. R. C. RAINEY and H. J. SAYER
Desert Locust Survey Headquarters, Nairobi

STANDARD methods of locust control, against the hoppers (nymphs), are applicable during only a small proportion of the total length of the life-cycle of the locust. The need for a method of attacking flying swarms has long been realized, and aircraft operations against swarms of the red locust (*Nomadacris septemfasciata* Serv.) in flight were undertaken in Central Africa as long ago as 1934[1]. Sodium arsenite was applied from a Hercules aircraft, and evidence was obtained that some locusts were on occasion killed in flight, but substantial improvements in equipment, insecticide and tactics were clearly needed.

Laboratory and field research directed to these ends has been in progress under the auspices of the Anti-Locust Research Centre for a number of years past. Aircraft trials in the Kenya Highlands in 1944[2] provided striking evidence of the unreliability of dusting against adult desert locusts (*Schistocerca gregaria* Forsk.), the 14 per cent dinitro-*ortho*-cresol (DNC) dust sometimes killing at well under 7 lb. per acre of settled swarm, but on other occasions failing to kill at more than 50 lb./acre; at the same time, these trials directed attention to relevant problems of locust behaviour[3] and of insecticide application[4], and led to the conception by Kennedy and Toms of the 'aerial curtain' method of attacking flying swarms. Following a preliminary theoretical examination, at the Chemical Defence Experimental Establishment at Porton, of the possibilities of this method, field-trials were carried out in Kenya in 1945 against desert locust swarms, using a 2½ per cent dinitro-*ortho*-cresol in oil spray from Baltimore aircraft[5]. On one occasion a kill of some 3 million locusts was recorded following the application of 300 gallons of spray to a flying swarm; and sufficient was learnt to encourage further research on these lines.

In 1947, a specially developed 20 per cent dinitro-*ortho*-cresol in oil spray was found highly effective in operations with Anson aircraft against settled red locust swarms in Tanganyika[6]. Complete kills were obtained at a dosage of slightly more than one gallon per acre, and in a single operation lasting less than two hours some 1,200 acres were 95 per cent cleared of locusts at a dosage of 0·7 gal./acre. The success of these operations was, however, made possible by a combination of favourable terrain, unusually sluggish locust behaviour, and large, well-organized and energetic ground parties for scouting and demarcation. Gunn[7], reviewing progress up to this stage, accordingly considered that suitable ground machinery might well have been cheaper and equally effective against settled swarms in such circumstances, and directed attention to the particular need for the development of aircraft methods of attacking swarms in flight, independently of ground parties; meanwhile, work on ground machinery suitable for large-scale operations against such settled swarms and against hoppers has continued[8].

During 1949 and 1950 the desert locust plague flared up again; and the mobility of the swarms of this species (which have not infrequently been known to breed more than a thousand miles from the area in which they had developed as hoppers) has been such that opportunities for utilizing large ground machines against settled adults of this species, in the manner in which such machines are regularly and effectively used against the red locust in its outbreak areas[8], have been rare indeed. Moreover, recent experience in India[9] has further emphasized the inevitable limitations of techniques of aircraft operation dependent on ground parties for scouting and demarcation, whether against swarms or hoppers.

Following preliminary aircraft observations in 1951 on certain relevant aspects of swarm behaviour, air-spray trials against flying swarms of the desert locust were resumed in Kenya on a small scale in 1952, financed by the Colonial Development and Welfare Research Fund. The scope of these trials was limited by a shortage of swarms; but during February 7–15, 1952, some 890 gallons of insecticide were applied to four immature flying swarms in the Northern Frontier Province in twenty-one sorties by a single Auster *J/1B* spraying aircraft (Fig. 1; 48-gallon spray-load and 130 h.p. Gipsy Major I engine), using a second Auster *J/1* for observation and reconnaissance, without ground scouting or demarcation.

Throughout the period of operations the swarms concerned travelled consistently down-wind; on all four occasions on which both upper-wind observations and accurate successive swarm fixes were available, swarm-track was within 1°–8° of directly down the corresponding vectorial mean wind between the ground and the level of the highest locusts. The down-wind movement previously shown to be a general characteristic of major long-distance swarm displacements[10] was thus also true in detail for the hour-to-hour swarm movements recorded during these trials. It was accordingly found possible to use the local early-morning pilot-balloon observations to determine the sector to be searched for incoming swarms, and every swarm was in fact first located, by systematic air search, while still approaching base,

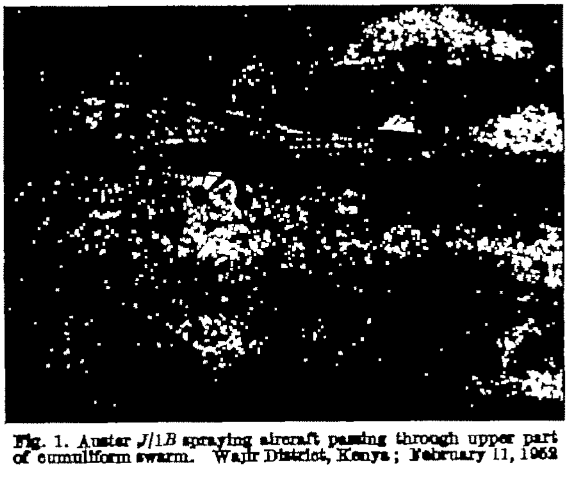

Fig. 1. Auster *J/1B* spraying aircraft passing through upper part of cumuliform swarm. Wajir District, Kenya; February 11, 1952

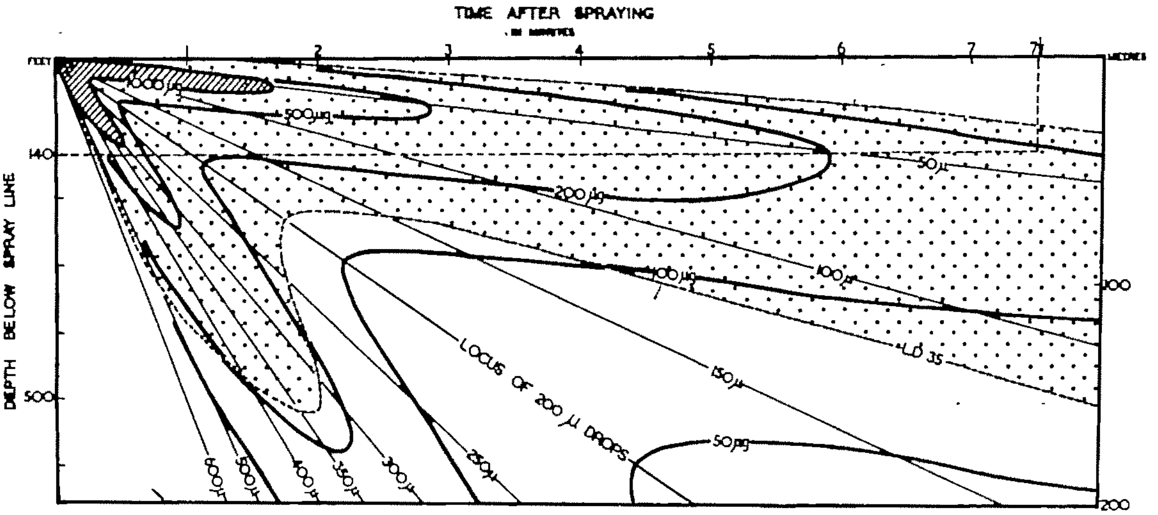

Fig. 2. Estimated dose of 20 per cent dinitro-*ortho*-cresol deposited on locusts flying at volume density of 0·1 per $m.^3$ through single spray-sheet given by drop-spectrum and emission-rate used during February 1952

giving ample opportunities for repeated spraying operations.

Such repeated attacks by highly manœuvrable light spraying aircraft have several advantages over corresponding single operations by larger aircraft, particularly against swarms of the complex structure seen in these trials (*vide infra*). Wastage of spray, both by overdosing and by missing locusts altogether, is more easily avoided with the light aircraft, with which the task of the spray pilot is simpler and expert direction accordingly less necessary. An important further advantage of the type of aircraft used was that the cooling system of the inverted in-line engine proved particularly well adapted to deal with incoming locusts, which accumulated harmlessly at the back of the air-scoop. Serious difficulties in this respect have been experienced in the past with, for example, radial engines[1,4]. The carburettor air-intake and oil-cooler were adequately protected by specially fitted wire grilles.

The ground-speeds of the swarms were very low (1–7 m.p.h.), as a result of the intermittent nature of the flight of the individual locusts, and were substantially less than the corresponding wind-speeds (7–21 m.p.h.). In such circumstances the original 'aerial curtain' technique[11]—making successive spray-runs between fixed air-positions across the heading of the locusts—was clearly inapplicable, since practically the whole of the spray applied in this manner would reach the ground far in advance of the swarm. The alternative 'static curtain'—produced by spray-runs applied between fixed ground-positions, initially ahead of the swarm—would clearly also waste most of the spray applied in the first few runs. Furthermore, with these low ground-speeds, a static curtain would need to be maintained for an excessively long time for the whole swarm to pass through it.

Fortunately, this type of swarm behaviour (movement down-wind at a ground-speed well below the wind-speed) had been encountered and studied during the preliminary aircraft observations in 1951, and it had been decided that such swarms should be attacked by drift-spraying, using the flying locusts for demarcation; but in fact treating the temporarily settled locusts beneath, which probably represent the greater part of such swarms, as the primary target.

The most complete evidence secured during the 1952 trials on the effects of aerial spraying was provided by the small fourth swarm, initially a mile long in flight and covering an area of 300–400 acres when densely settled, which was almost completely destroyed by the application of 340 gallons of 20 per cent dinitro-*ortho*-cresol from heights of 50–400 ft. above the ground in the course of nine sorties. No rigorous assessment of mortality was possible, owing to the terrain (*Acacia* – *Gyrocarpus* – *Delonix* – *Boscia* dry woodland with *Commiphora* – *Cordia* thorn-bush, giving a total canopy approaching 40 per cent), and to the distance covered by the swarm during the spraying operations (49 miles); but the survivors which were actually seen (settled, mainly very thinly, over an area of no more than an acre) did not appear to amount to 0·1 per cent of the original swarm. Furthermore, these results were obtained under what had previously been considered unfavourable conditions, in respect both of swarm behaviour and of weather[5,12]. Thus all four swarms flew for the greater part of each day in rolling cumuliform formation, with some locusts at times up to 2,000 ft. above the ground, and many others temporarily settled beneath the swarm. Air temperatures up to 101° F. and relative humidities down to 25 per cent were encountered during the all-day operations, with vigorous convective turbulence; counting accelerometer[13] records during spraying averaged nine up-gusts per mile exceeding an equivalent vertical air velocity of 0·8 m./sec.—the terminal velocity of 220-μ drops.

Records, mainly photographic, of the density and orientation of the flying locusts, and other relevant observations taken during these trials, made it possible to assess the field-results obtained in relation to the latest Porton data[14] on spray pick-up and toxicity of dinitro-*ortho*-cresol to flying locusts under controlled wind-tunnel conditions, using the convenient method of graphical analysis developed by Sawyer[15].

The evidence thus obtained on the probable distribution and effect of the spray within a swarm is illustrated by Fig. 2, computed for the drop-spectrum used during the trials (with a mass median diameter determined by the Colonial Insecticide Research Unit as 220 μ), the corresponding emission-rate (30 gal./min. at 85 m.p.h. T.A.S.), and a swarm density of 0·1 flying locusts/$m.^3$, which may be regarded as representative of the denser parts of the swarms sprayed in 1952. The contours indicate the dose picked up by locusts flying through the spray-sheet on courses perpendicular to the latter; at a depth below the spraying aircraft and a time after spraying corresponding respectively to the ordinate and abscissa of the appropriate point in the diagram. The area within a particular contour in such a diagram gives a direct measure of the number of locusts dosed to at least the contour figure, and, if this figure be chosen to give an appropriate mortality, an estimate of kill can be obtained. The dose figure required for such an estimate of kill is one such that the number of locusts killed under the given conditions by doses smaller than this is equal to the number of locusts surviving doses larger than this figure. Now the numbers of locusts dosed to a particular level are, at the relatively low densities so far encountered, roughly inversely proportional to the square of the dose. The required contour value is accordingly liable to be appreciably below the median lethal dose (*LD* 50 per cent); and its actual value will depend on the exact relationships between dose and mortality and between dose and relative numbers treated for the insecticide and conditions under consideration. From dose/mortality data for this particular dinitro-*ortho*-cresol formulation, applied to flying desert locusts at a representative range of drop-sizes[14], and the relationship between dose and relative numbers treated under the conditions of the trials, determined graphically from diagrams such as Fig. 2, the value appropriate to these conditions has been estimated to be about *LD* 35 per cent. This corresponds to a spray pick-up ranging from 45 μgm. per locust for 100-μ drops to 220 μgm. per locust for 350-μ drops[14]. Fig. 2 shows a *LD* 35 contour constructed in this manner, enclosing a stippled area which provides a measure of the kill.

The treatment so far assumes that all the locusts fly straight through the spray-sheet on a heading perpendicular to the latter, while the actual swarms sprayed exhibited a characteristic diversity of orientation. Sawyer's treatment may be extended to cover such behaviour by considering the extreme case of completely random orientation, with locusts flying on all possible courses. It is readily shown that such randomly orientated locusts may be expected to pick up an average dose $\pi/2$ times greater than that picked up by locusts flying perpendicularly through the same part of the same spray-sheet, but that at constant locust density the number of randomly orientated locusts passing through a given spray-sheet in unit time (or, since attenuation[11,15] can be shown to be unaffected, during the whole effective life of the spray-sheet) will only be $2/\pi$ or 64 per cent of the number which would pass through it on a perpendicular orientation. Under the conditions of the trials, orientation was not in fact completely random. Flight in groups, each of relatively uniform orientation, but with very large differences in orientation from time to time and from group to group within the swarm, such as were actually seen, would have the same effects as random orientation when the number of groups is sufficiently large and all orientations are equally represented. But indications of an occasional local predominance of either up-wind or down-wind orientations (which would have been perpendicular to the spray-sheet) suggest that conditions may be regarded as having been intermediate between the case of completely random orientation and that of orientation perpendicular to the sheet.

Before proceeding with an estimation of the kill to be expected from a particular operation, one further limiting condition must be defined: the length of time during which the spray-sheet continues to affect the swarm, through which it passes with the corresponding relative wind. This will depend not only upon the relative wind, but also on the size of the swarm, and on the position of the spray-run (always made at right angles to the relative wind) in relation to the swarm as a whole. Without much more precise recording of the progress of each operation than was practicable at the time, some uncertainty is inevitable on this latter point; but it is considered that an overall assumption that each spray-run was made across the centre of the swarm is, on the average, unlikely to be seriously in error.

The accompanying table summarizes graphical estimates of total kill for the particular operation for which information was most complete, though, from the evidence available on the density of the flying locusts, it is only possible to say that the mean volume density of the locusts sprayed is likely to have been between 0·01 and 0·1 per cubic metre. Spraying height was 140 ft. above the ground (and well below the topmost locusts), the emission-rate recorded on this occasion was 20 gal./min., and the swarm was travelling down-wind at a ground speed of 3 m.p.h. in a wind of 7 m.p.h. It was about a mile long, giving with a relative wind of 4 m.p.h. an effective duration of about 7½ min. for each spray-sheet. With an area of about two-thirds of a square mile, a mean area density of the order of 1–10 flying locusts per square metre of plan area of the swarm, and only something like 40 per cent of the locusts in flight at once, the size of the whole swarm may be estimated as between five and fifty million locusts. With this estimate may be compared the figures for the estimated total kill resulting from the particular operation under consideration, ranging from 1·4 to 19 million (see table); the swarm was almost completely destroyed by seven such operations.

SUMMARY OF GRAPHICAL ANALYSIS OF A SINGLE SPRAYING OPERATION

02° 01′ N., 40° 24′ E., 15·51–16 07 E.A.S.T., February 14, 1952

Graphical estimates of kill

	Orientation of flying locusts: random	Orientation of flying locusts: perpendicular to spray-sheet
For volume density of 0·1 flying locusts/$m.^3$	$1·3 \times 10^7$	$1·9 \times 10^7$
For volume density of 0·01 flying locusts/$m.^3$	$1·4 \times 10^6$	$2·2 \times 10^6$

Cf. total size of swarm, estimated to contain $0·5–5 \times 10^7$ locusts, and almost completely destroyed by seven such operations.

Graphical estimates of numbers dosed to 1,000-μgm level

	Random orientation	Orientation perpendicular to spray-sheet
For 0·1 locusts/$m.^3$	$1·2 \times 10^6$	$0·8 \times 10^6$
For 0·01 locusts/$m.^3$	$1·2 \times 10^5$	$0·8 \times 10^5$

Cf. independent estimate of 10^5–10^6 locusts dosed to this level, from corpse counts.

Furthermore, remains of 1,471 dead locusts, more than 99 per cent of them visibly contaminated with dinitro-*ortho*-cresol, were found at eighty sample points over an area 1,100 yd. across and extending for 2·6 miles along the track of the swarm from this spray-site; and, while both sampling and searching were severely restricted by terrain and time, it was possible from the counts made to estimate the total dead within the area of the site examined as between 10^5 and 10^6. Chemical assessment of the degree of contamination of these locusts was not practicable; but a detailed visual assessment, in conjunction with laboratory data on the relationship between drop-size and such stain-sizes on locusts[14], indicated a mean level of contamination of the order of 1,000 µgm. per locust (incidentally suggesting a degree of over-dosing which is consistent with the fact that all these locusts must have dropped out of the swarm within about an hour after spraying). The graphical treatment gave estimates (see table) of the number of locusts dosed to at least 1,000 µgm. during this operation (corresponding to the shaded area in Fig. 2) ranging from $0{\cdot}8 \times 10^8$ to $1{\cdot}2 \times 10^9$, which may be compared with the independent estimate, given by the corpse counts, of 10^8–10^9 locusts dosed to about this level.

The graphical treatment thus gave figures which were clearly of the right order. The total kill of flying locusts, and the numbers over-dosed to a particular level, as estimated from laboratory data and theoretical considerations, both agreed, within the admittedly wide limits inherent in the nature of the field-observations, with the results actually observed. It was accordingly worth while to examine some further implications of the graphical analysis. In particular, the efficiency of this individual operation, estimated by comparing the figures given for total kill with that theoretically possible by applying the complete spray-load of 48 gallons to flying locusts in 100-µ drops at the corresponding median lethal dose of 60 µgm.[14], was only between 0·1 and 1 per cent.

In the first place, spraying-height (considered at the time only in relation to the settled locusts then regarded as the primary target) was too low (140 ft.; see Fig. 2); the spray will have reached the ground at concentrations which would still have been effective against fliers down to some 500 ft. below the aircraft. Spraying tactics clearly required modification, in order that on each spray-run the lethal zone indicated by the graphical analysis should correspond as far as possible with the main concentrations of flying locusts seen. Incidentally, even the peak ground-contamination from each spray-run during this operation is only likely to have been about ¼ gal./acre—insufficient in fact either to have given an effective kill of the more resistant settled locusts (*vide infra*), or to account for the degree of contamination of the dead locusts seen, which must accordingly have been sprayed in flight. Furthermore, the modifications indicated in spraying tactics correspond to still lower levels of ground-contamination, at which phytotoxicity effects[17], and potential dangers to man and stock (even if directly exposed), become vanishingly small.

In the second place, the kill obtained was very largely due to the smaller drops, the graphical treatment attributing some 80 per cent of the kill to drops smaller than 100 µ, which comprised less than 30 per cent of the total volume of this particular spray. While such drops are, of course, particularly vulnerable to displacement by turbulence, the grosser manifestations of turbulence may to a first approximation be expected to affect spray and flying locusts alike when the former is actually emitted among the latter (Fig. 1); and a finer spray was accordingly indicated. This point—and the greatly enhanced susceptibility attributable to flight—are strikingly illustrated by the area dosages for a 99 per cent kill, which for isolated flying locusts may be computed from the data of ref. 14 to require under ideal conditions only 0·02 gal./acre with 100-µ drops, 0·1 gal./acre with 200-µ drops, and 0·9 gal./acre with 500-µ drops, compared with the corresponding dosage of 1·1 gal./acre needed for a similar kill of completely settled locusts[18].

Thirdly, it would appear that *LD* 50 (or perhaps even *LD* 35) may be a better criterion for air-spray insecticides than the *LD* 99 figures previously used. The necessary laboratory tests on flying locusts have so far been carried out only with dinitro-*ortho*-cresol[14]; but in tests using a different (and therefore not necessarily relevant) method of application (by micro-drop syringe), γ-benzene hexachloride (BHC), for example, has been found to compare considerably more favourably with dinitro-*ortho*-cresol at the *LD* 50 than at the *LD* 99 level[19].

Further trials along the lines so indicated were financed by the Desert Locust Control Organization and undertaken the following season, using a drop-spectrum with a mass median diameter of 140–150 µ instead of 220; tactics were directed at the flying locusts instead of at the settled ones; and small quantities of a γ-benzene hexachloride concentrate were used as well as dinitro-*ortho*-cresol. Between December 30, 1952, and January 31, 1953, 3,045 gallons of concentrated insecticide were applied to fourteen small immature and maturing swarms in flight during ninety-three sorties (totalling 97 hr. flying) by two Auster *J/5G* spraying aircraft (155 h.p. Cirrus Major III engine and 78-gallon spray tank) operating from four successive bases extending over some four hundred miles across Kenya, with the assistance of a third Auster for observation and recon-

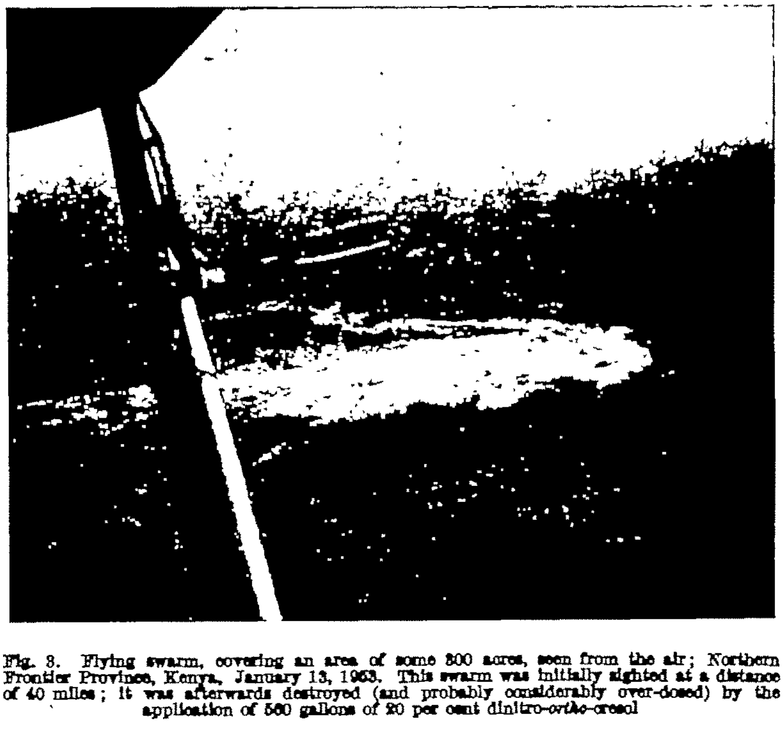

Fig. 3. Flying swarm, covering an area of some 300 acres, seen from the air; Northern Frontier Province, Kenya, January 13, 1953. This swarm was initially sighted at a distance of 40 miles; it was afterwards destroyed (and probably considerably over-dosed) by the application of 560 gallons of 20 per cent dinitro-*ortho*-cresol

naissance (representing a further 94 hr. flying), but again without ground parties for scouting or demarcation. Data were also secured on the economics of such operations; the total cost of chartering the three aircraft (terminal charges, overheads and flying charges over the whole period December 1, 1952–February 14, 1953, including 179 hr. additional experimental, reconnaissance and communications flying) was £4,400, to which should be added £1,600 in respect of the insecticide used and £2,600 in respect of the total ground expenses of the unit over this period.

The results confirmed and extended those of the previous season. Repeated air observations of four of the sprayed swarms, each initially covering 300–500 acres in flight in rolling cumuliform formation, and at times visible up to forty miles away (Fig. 3), demonstrated the striking effects of spray-rates totalling about 1 gallon dinitro-*ortho*-cresol per acre of flying swarm; all four swarms were reduced to small groups of survivors, found only with considerable difficulty and no longer worth spraying. It has incidentally since been learnt that dinitro-*ortho*-cresol spraying from aircraft is also now in use, on a substantial scale, against flying and settled swarms of *Schistocerca paranensis* Burm. in the Argentine[20].

Circumstances exceptionally favourable for ground assessment on one occasion during the Kenya trials made possible for the first time a direct assessment of the total kill resulting from a single spraying operation of this nature. Thus, following the application of 50 gallons of 11 per cent γ-benzene hexachloride to a low-flying maturing swarm between 16.50 and 17.20 hr. on January 27, 1953, over open ranching country between Nanyuki and Thompson's Falls in the Kenya Highlands, the swarm settled for the night only two-thirds of a mile beyond the spray-site, and the survivors did not move off until shortly before noon the following day. Practically the entire kill resulting from this operation accordingly took place within the 200 acres of grassland, with scattered *Acacia drepanolobium* and *Scutia myrtina*, which comprised the roosting site, instead of being scattered along many miles of thick thorn-bush as after all previous operations. Counts at 101 sampling points of 1 sq. yd. each, located to provide a valid composite sample of the whole roosting site, gave a mean and standard error of 38 ± 5·8 dead per square yard, corresponding to a total kill of 37 ± 6 million locusts. The net cost of this operation, including all flying and ground expenses of the unit over the period from the initial air-search for this swarm until the final spraying sortie, was £195. However, while between sixty and eighty tons of locusts had thus been killed at a cost of about £3 per ton by 50 gallons of insecticide containing 75 lb. of active ingredient, the actual efficiency of the operation, estimated approximately by comparing the kill obtained with that corresponding to the application of the same quantity of insecticide to the vertex of *Locusta* at the median lethal dose[19], was still only 1·5 per cent. This figure provides some indication of the scope still remaining for improvements in the technique; and, as has been indicated, effective methods are now available for the logical development of appropriate spraying equipment and tactics[15], and for the accurate assessment of new insecticide materials against flying locusts under controlled conditions[14]; also studies on meteorological factors in relation to swarm movements (refs. 10, 21, etc.) have begun to provide a rational basis for the short-period tactical forecasts of swarm movements essential for effective operations of this nature.

A fuller account of the 1951–53 trials and of the associated observations on locust behaviour is to be prepared for publication elsewhere. We should like to express our very warm appreciation of the assistance provided by our colleagues of the Desert Locust Survey and Control Organization, both in the field and at headquarters, and of the active co-operation of members of the staffs of the Anti-Locust Research Centre, the Chemical Defence Experimental Establishment, the Colonial Insecticide Research Unit (Tanganyika), the Royal Aircraft Establishment, the East Africa Meteorological Department, the Kenya Medical Department, the administration of the Northern Frontier Province, the Biochemistry Department of the University of Liverpool, Messrs. Aerial Spraying Contractors, Ltd., of Boston, Lincs, and Messrs. Pest Control, Ltd., of Cambridge, which has made this work possible.

CHANGES IN THE MORTALITY-RATE DUE TO MYXOMATOSIS IN THE AUSTRALIAN WILD RABBIT

By PROF. FRANK FENNER, M.B.E.

Australian National University, Canberra, Australia

RATCLIFFE and his colleagues[1] have described the violent epizootics of myxomatosis which occurred among Australian wild rabbits in the summers of 1950–51 and 1951–52. During the summer of 1952–53 there were again epizootics over the greater part of south-eastern Australia, and the rabbit population is now at a lower level than it has been since the great droughts of 1919 and 1945[2]. During the past few months, however, there have been reports from a few areas that an increasing number of affected rabbits were recovering from the disease. In this note an attempt has been made to assess the evidence for these reports, and possible mechanisms of recovery from myxomatosis are discussed.

All reports of myxomatosis in *Oryctolagus cuniculus* have emphasized the very high lethality of the disease. Recoveries are extremely rare among laboratory rabbits; but often massive doses have been used for infecting these animals. In contact infections, and inoculations with small doses of virus in 560 laboratory and English wild rabbits, Martin[3] observed ten recoveries out of 312 cases infected with one strain of the virus, three out of 248 with another strain. Bull and Mules[4] noted two recoveries in 929 wild Australian rabbits exposed to infection in a colony maintained by the regular addition of normal animals.

Accurate information upon population densities of wild rabbits in the field is difficult to obtain in Australia; but Myers[5] recorded reductions from 5,000 to 50 and 500 to 12 in two areas in which rabbits were subjected to their first exposure to the disease. Regular counts were made on standard walks. In adjacent areas it was found that about 25 per cent of the survivors gave serological evidence of previous infection. Applying this figure to the relict populations, one obtains case-mortality-rates of 99·4 per cent and 99·8 per cent, which agree closely with that recorded by Bull and Mules in the colony experiment[4].

In a few areas in which extensive outbreaks with very high mortalities had occurred in the summer of 1950–51 the performance of the disease was disappointing in 1951–52. Scattered cases occurred in the population which had built up during the winter and spring of 1952, but although the vector situation seemed adequate to ensure another violent epizootic this did not occur. Sampling of these populations and tests of the sera for antibodies to myxoma virus revealed that the majority of the surviving rabbits had recovered from infection[6]. In these areas there had been widespread infection, but a relatively small proportion of the infected rabbits had died.

During 1952–53 field investigations were for the most part concentrated in a few areas in which regular observations of the rabbit populations could be maintained by officers of the Wildlife Survey Section of the Commonwealth Scientific and Industrial Research Organization. In the summer of 1952–53 there were once again widespread and violent epizootics of myxomatosis over the greater part of south-eastern Australia. In a few localities the kill was low in spite of the observation of many diseased rabbits, and serological surveys at the end of the summer revealed the occurrence of very widespread infection. A brief description of one of these outbreaks indicates the nature of the observations[6]. Noorong Station, in the Riverina area of New South Wales, has an area of 20,000 acres. During 1950–51 and 1951–52 violent epizootics of myxomatosis occurred and the rabbit population was reduced to a very small proportion of its size prior to the introduction of the disease. In spite of some breeding during the winter the rabbit population in November 1952, when the disease appeared again, was much smaller than at corresponding periods in previous years. Just before Christmas the station manager reported that it was almost impossible to see a rabbit on the property which did not appear to be infected. By the middle of January many of the rabbits seen in the paddocks had obvious signs of recovery from myxomatosis. The kill was assessed by the station manager as 25 per cent; but this was almost certainly an underestimate. Nevertheless, the kill did not approach the figure of 90 per cent or more noted during the previous two years. The sera of the twenty-five rabbits tested after the outbreak contained antibodies to myxoma virus.

There are several possible explanations of the altered case-mortality-rates, and the position is complex because of the differing importance of the factors to be discussed in different areas.

Immunological

Myxomatosis in the European rabbit is a generalized disease associated in the late stages with an extensive rash[7]. Free antibody is rarely found in the serum of laboratory rabbits infected with virulent myxoma virus, for even with minimal inocula they usually die by the ninth or tenth day. Free antibody could be found in the sera of animals receiving small inocula of neuromyxoma virus[8], however, eleven days after infection[7]. Serial bleeds on some recovered wild rabbits obtained after the 1950–51 epizootic showed that detectable antibody persisted, at a relatively high titre, for at least eighteen months, and was accompanied by a high degree of resistance to re-infection[6].

British ecologists[9,10] believe that few wild rabbits survive under natural conditions for more than a year. If this were the case in Australia the population exposed to the annual summer epizootics might be expected to be almost universally susceptible. During the past year regular sampling of rabbit populations and serological tests have revealed that an appreciable number of rabbits which have recovered from one epizootic survive long enough to be exposed to the next one. The population count in one of the areas mentioned earlier in this article was 550 at the outset of the 1952–53 epizootic, compared with 5,000 at the same period a year earlier[11]. Sampling at the commencement of the epizootic indicated that 23 per cent of the population were survivors of the 1951–52 epizootic, and one-third of these, or 8 per cent of the total population, were immune. The pre-epizootic population of 550 might thus be considered to consist of about 500 susceptible and 50 immune rabbits. The count at the end of the epizootic, one month later, was 77, and serum sampling of a nearby area at this time showed that all the remaining rabbits had antibodies to myxoma virus. Forty per cent of these were rabbits more than a year old. Thus there was a population reduction of 500 susceptible to 46 recovered rabbits, that is, a 92 per cent case-mortality-rate. This may be compared with the figure of 86 per cent calculated from the uncorrected figures (550 to 77). The accumulation of immunes thus plays some part in the diminished kills recorded. It may be expected to play a larger part in the next epizootic, for in this area (as in many others) practically all the surviving rabbits have recovered from the disease.

Another immunological mechanism which may be of importance is the infection and active immunization of a proportion of kittens infected while they still possess antibodies derived from their immune mother. This is probably of major importance in the maintenance of mousepox in populations of laboratory mice, with only occasional fatalities[12]. Current experiments[13] indicate that kittens borne by myxoma-immune mothers retain detectable serum antibody and exhibit a modified response to infection for at least six weeks after birth. The number of recoveries occurring in laboratory experiments has been small, but there has always been a considerable prolongation of the survival-time. Field observations made so far, and the common occurrence of the disease as explosive summer epizootics several months after the main breeding season, minimize the possible importance of this phenomenon, but it is of potential importance, especially if there were slight changes in the virulence of the virus or the genetic resistance of the host, or in areas in which active transmission occurred during the breeding season.

Genetic Changes in the Virus

Experiments with the fibroma–myxoma 'spectrum' of viruses[14] indicate that there are wide variations in the virulence of these viruses. Two variants of myxoma virus with lowered virulence have been isolated in the laboratory: Hurst's neuromyxoma[8] and Berry's 80*A* mutant[15]. Tests with the former variant have shown that it rarely causes death in laboratory rabbits infected with minimal doses, and that it is spread by mosquito biting only with considerable difficulty[16]. Mykytowycz[17] has recently recovered from a wild rabbit caught near Canberra a strain of myxoma virus which failed to kill any of the nine wild rabbits infected by contact. This strain, and other strains obtained in 1953 from several different localities in Australia, have allowed prolonged survival of laboratory rabbits infected with small doses of the virus, and an occasional recovery, and are undoubtedly slightly less virulent than the standard laboratory strain[12]. Several of these variants of slightly reduced virulence were recovered from mosquitoes captured in the area in which there was a 99·8 per cent case-mortality-rate in 1951–52, and a 92 per cent case-mortality-rate in 1952–53. It is likely that this reduction was due in part to the presence of this altered virus.

The future spread of such variants of reduced virulence is problematic. If, like neuromyxoma, they combine diminished virulence with a diminished capacity to multiply in epidermal cells, it is unlikely that they will spread readily enough to supplant the fully virulent virus. A variant which combined diminished killing capacity with the ability to attain high concentrations in the skin would be likely to spread.

Genetic Changes in Host Resistance

The Australian wild rabbit reacts differently from the laboratory rabbit to inoculation with the same dose of myxoma virus. The development of the disease appears to lag about one day behind what is found with laboratory rabbits. It is conceivable that there might be a fortuitous variation in innate resistance to myxomatosis in the wild rabbits in different areas of Australia, and this might account for different case-mortality-rates even on first exposure to the virus. It seems inevitable that the drastic selection imposed by myxomatosis will within a few years alter the genetic resistance of the Australian wild rabbit. In the absence of any knowledge of the heritability of innate resistance it is impossible to say how rapidly this process might occur, and whether it could within two or three generations cause detectable differences in the case-mortality-rates.

Environmental Factors

Two environmental factors are known which affect the mortality-rate in myxomatosis: the effects of continued high temperature[18], and concurrent infection with certain neurotropic viruses[19]. Continued day and night temperatures of 37° C. have not occurred under natural conditions; but the possibility that intermittent exposure to high environmental temperatures might permit the recovery of some infected animals has not yet been tested.

The Australian neurotropic virus (Murray Valley encephalitis virus) has been found to interfere with fibroma virus in a manner analogous to that described with Semliki Forest virus[20], and it is likely that a similar effect would occur with myxoma virus. However, the absence of MVE virus from southern Australia since 1951[21] precludes the possibility that this has been an important factor in the field.

Conclusion

Field observations supplemented by serum surveys have revealed that in some areas the case-mortality-rate in myxomatosis has been lower than that observed after the first impact of the disease in many parts of Australia. Survival through a second epizootic of some of the survivors of the first epizootic contributes to this result, but cannot account for it completely. During the past year variants of the virus of slightly diminished virulence have been isolated from natural cases of the disease and from mosquitoes captured in epizootic areas. The epidemiological significance of attenuated variants depends upon their ability to spread through the rabbit population; but their recovery from several samples of mosquitoes caught during epizootics in the Murray Valley suggests that in certain areas they may have replaced the original 'standard laboratory strain' with a consequent slight reduction in the case-mortality-rate. Genetic changes in the innate resistance of the rabbit population may have occurred but have not yet been demonstrated experimentally. It is not yet possible to forecast the long-term significance of these observations. Falling case-mortality-rates in greatly reduced rabbit populations will certainly occur, due to the accumulation of immune animals. Genetic alterations in either or both the virulence of the virus and the innate resistance of the host may be expected to occur, and may, in a sporadic manner, further reduce the case-mortality-rate. In spite of these changes, however, myxomatosis may permanently reduce the rabbit population in Australia, so that it attains a balance at a very greatly reduced population density.

NEWS and VIEWS

Plant Biophysics at Leeds: Prof. R. D. Preston

Dr. R. D. Preston, whose appointment to the newly created chair of plant biophysics in the Botany Department at the University of Leeds has recently been announced, is one of the few scientists with an initial training in pure physics to make a career in botany. He graduated with first-class honours in physics at Leeds in 1929 but immediately began research, by invitation of the late Prof. J. H. Priestley and later in collaboration with Prof. W. T. Astbury, on fundamental botanical problems, notably those of cell wall molecular architecture and sap ascent. He spent the first seven years after graduation in association with the Botany Department as a holder of various postgraduate research awards, which included a Senior D.S.I.R. Studentship, an 1851 Exhibition Fellowship and, in 1935–36, a Rockefeller Foundation Fellowship which took him to Cornell University and gave him the opportunity of spending a year in strictly botanical work under Sharp, Eames and Curtis. On his return from the United States, Preston joined the teaching staff of the Botany Department, giving lectures in all aspects of plant physiology and in a number of general courses including plant morphology and elementary courses. He was promoted successively from lecturer to senior lecturer and eventually to reader.

Preston's readership coincided with the establishment of the Sub-department of Plant Biophysics by means of a substantial grant from the Department of Scientific and Industrial Research for basic equipment, including an electron microscope, in 1948. Plant biophysics as a normal teaching subject for undergraduates in botany had been introduced the year before. Preston's research output includes numerous papers on cell wall structure and sap ascent together with several more general articles in publications such as *Science News*, *Fibre Science*, the "Symposium on Deformation and Flow in Biological Systems", "Advances in Biophysics", etc. His own work has recently been summarized in his book "Molecular Architecture of Plant Cell Walls" (1952). He has lectured on biophysical subjects in the United States, Holland, Sweden, France and Italy, and in the more strictly biological field he has acted for many years as external examiner in biology for the Yorkshire teachers' training colleges. His promotion now to a chair in his own University is a fitting tribute to an outstanding achievement and a good augury for the maintenance of the fine traditions of the Leeds Botany Department.

Committee on Air Pollution

In reply to questions in the House of Commons on July 21, Mr. A. E. Marples, Parliamentary Secretary to the Ministry of Housing and Local Government, announced that the Minister, with the Secretary of State for Scotland and the Minister of Fuel and Power, has appointed a committee "To examine the nature, causes and effects of air pollution, and the efficacy of present preventive measures; to consider what further preventive measures are practicable; and to make recommendations". The committee will be assisted in its work by assessors from the Ministry of Housing and Local Government, Ministry of Fuel and Power, Ministry of Health, Department of Scientific and Industrial Research, Department of Health for Scotland, and Welsh Board of Health, and will begin work forthwith. The members of the committee are: Sir Hugh Beaver (*chairman*); Miss A. D. Boyd, housing manager, Rotherham County Borough Council; Dr. J. L. Burn, medical officer of health, Salford County Borough Council; S. R. Dennison, Fellow of Gonville and Caius College, Cambridge; Sir Roger Duncalfe, chairman of British Glues and Chemicals, Ltd., chairman of the Federation of British Industries Technical Legislation Committee and vice-president of the Federation of British Industries; Prof. T. Ferguson, professor of public health and social medicine, University of Glasgow; Dr. G. E. Foxwell, president of the Institute of Fuel; Dr. R. Lessing; G. Nonhebel, Imperial Chemical Industries, Ltd.; C. J. Regan, chemist-in-chief, London County Council; and Prof. O. G. Sutton, chairman, Atmospheric Pollution Research Committee.

University College, Ibadan: Report of the Visitors

The report of the Visitors to University College, Ibadan (pp. 42; from the College), covers a visit made during December 30, 1951–January 12, 1952, but also comments briefly on some subsequent developments. The Visitors (C. R. Morris, J. E. Harris and W. Adams) were impressed with the excellent start that the College has made. Although it does not enjoy full public confidence, the success of the College is of vital importance to Nigeria, and Ibadan is the necessary first step towards a Nigerian university. Of the three major problems facing the College at the time of the visit, those of the future policy for the Medical School and of finance are well on their way to solution through subsequent developments; that of academic self-government remains. The immediate tasks before the College, as seen by the Visitors, are first to strengthen its unity and to resist tendencies to fragmentation. Here the Academic Board can play a decisive part by taking up its full responsibilities and providing a strong unifying influence. The second task, to consolidate the gains made during the first four years of rapid growth, is one for the administrative as well as for the academic staff, and the student body. The third is to work out a long-term guiding plan of academic development and priorities, understood and agreed by the whole College, so that each new commitment it undertakes can be seen and judged against the background of a considered and balanced scheme of development. The Visitors point out that both the College and its staff are young and vigorous and that it has much to gain by retaining its youthfulness by giving every opportunity to the junior staff to play a full part in the work of the College and, in its staff recruitment, by continuing to attract young men and women to senior as well as junior positions. The fourth task is to establish the reputation of the College so that it enjoys the full confidence of responsible Nigerian opinion, and has a public standing and national support worthy of its position as the first university institution in Nigeria. The College is financially most vulnerable in its recurrent income; but a substantial increase in its endowment income has since been provided in a sum of £1·5 million voted as expendable endowment by the Government of Nigeria.

Wattle Research Institute, University of Natal: Report for 1951–52

The report of the Wattle Research Institute, University of Natal, for 1951–52 (pp. 76. Pietermaritzburg: University of Natal, 1952) is more than the usual annual one, as it is now issued in August instead of January to coincide with the financial year of the Wattle Growers Union. The change, says the report, has enabled work in progress to be reported up to a well-defined seasonal phase and has allowed the writing-up to be done at a time of the year when the demands of field work are less insistent—points which will be understood by all field practical research workers. Considerable work has been carried out on the buildings of the Institute and the lay-out of the farm, with a planned road system which will comprise some twenty-two miles when completed. Some eighty acres of the farm have now been planted for experiments. Improvements have been made to the nursery, and a small plantation of black wattle has been established to facilitate *ad hoc* tests of the effect of insecticides, weed-control chemicals, and so forth. Part 1 of the report deals with administration, and Part 2 with research, including sylviculture, genetics and plant breeding, chemistry and entomology. Progress reports include one by H. Shaw, the director of the Institute, entitled "Natal, Home of the Union Wattle Industry". Filling of research-staff posts has proved somewhat difficult, especially the junior posts, in which there is a high wastage of junior assistants owing to resignations after a short period of service. Improved conditions of service are now being introduced.

Carnegie Trust for the Universities of Scotland: Annual Report for 1951–52

The fifty-first annual report of the Carnegie Trust for the Universities of Scotland (pp. 80; Carnegie Trust, Edinburgh, 1953) covers the academic year 1951–52 and includes the following items: the abstract of accounts; a summary of grants for the period October 1, 1952–September 30, 1957; a report upon the work of investigators under the research scheme during the year; a list of publications by fellows, scholars and recipients of grants since September 30, 1951; a list of awards for the year 1952–53; and details of assistance to students. Of the £37,365 distributed on research schemes during the year, £19,395 went to fellowships and scholarships; £4,000 in block grants to the four universities, for use at their discretion in assisting professors, readers, lecturers and assistants on research projects during vacations; £2,645 to the new scheme by which not more than ten specially selected members of the university staffs were given opportunity for travel and maintenance abroad on research; and £8,160 for grants in aid of research. £3,165 was set aside to give partial guarantee against loss on publication of works of high merit. Reverting to the pre-war practice of utilizing for current income the annual interest from the general reserve fund and the fund founded from repayments by former beneficiaries (which increased during 1951–52 to £1,985 from thirty-six former beneficiaries), the executive committee from an annual income of approaching £127,000 offered to the Universities of St. Andrews and Aberdeen £50,000 in all, spread over the next quinquennium, 1952–57, subject to approval of the proposed use by the committee. £80,000 each was similarly offered to the Universities of Glasgow and Edinburgh, with £23,000 during the period to the extra-mural colleges. In regard to applications for fellowships and scholarships, the executive committee points out that a number of applications received should more properly have gone to the Department of Scientific and Industrial Research. The scheme for the endowment of postgraduate study and research is appended to the report, and the committee directs attention to the second paragraph of the scheme which indicates that where science scholarships are concerned, more especially in physics and chemistry, the committee reserves the right to give preferential treatment to applicants ineligible to receive allowances from the Department of Scientific and Industrial Research.

Journal of Histochemistry and Cytochemistry

Two numbers of the new *Journal of Histochemistry and Cytochemistry* have now appeared. The new journal is edited by R. D. Lillie for the American Histochemical Society and is published by Williams and Wilkins (£3 a year, post-paid). There will at present be six numbers a year, giving an aggregate of about 500 pages per volume. Manuscripts, books for review and all inquiries concerning material should be addressed to Dr. R. D. Lillie, National Institutes of Health, Bethesda 14, Maryland, U.S.A. At present, papers on histochemistry and cytochemistry are widely scattered through the literature. No doubt this will continue to be the case; but workers in these fields will welcome a journal which is primarily devoted to cytochemistry, particularly if the new journal concentrates on methods. Papers which are primarily studies of biological problems, and which incidentally make use of histochemical and cytochemical methods, will more properly find their places in older journals. But there is a great field of investigation of cytochemical methods, much of which is highly controversial: studies in this field will find a more appropriate home in the new journal. Each number of the new journal will also include a list of current papers on histochemistry published in other journals.

Royal Scottish Museum, Edinburgh: Report for 1952

The annual report of the Royal Scottish Museum for 1952, while recording the normal activities of display and the systematic arrangement of reserve material, emphasizes the important part played by the staff in various educational and cultural organizations. To mention only a few examples, the director, Dr. D. A. Allan, is one of the two British members of the executive of the International Council of Museums and acts as assessor and consultant in connexion with the award of Carnegie grants to Scottish Museums; Mr. Cyril Aldred is honorary secretary of the Scottish Federation of Museums and Art Galleries; and Dr. A. C. Stephen acts as examiner for the diploma of the Museums Association. The sum total of the activities of the staff in local, national and international organizations forms an impressive record.

United States National Museum

The annual reports of the United States National Museum for 1951 and 1952 well illustrate the balance it is always necessary to keep in a well-planned museum between direct and indirect service to the public. Direct service is through exhibits, talks to visiting groups, answering of inquiries; while the indirect service to the community is through the cataloguing, indexing and research on the collections. From the point of view of the staff of a museum, it may be said that the effective performance of both these functions depends on that essential element in the work of a successful museum, namely, research.

Realizing this, the United States National Museum at Washington concentrates on research, and its annual reports form an impressive record of the work of the staff in this important direction. The scope of these investigations is so large that it is perhaps invidious to particularize; but mention might be made of the excavation of a large Cheyenne village in South Dakota where the evidence helped to interpret the role of Indian tribes before and during the early historic colonization. Reports have also been prepared on mammals recently collected in northern Australia, in arctic America and in the eastern United States, and also on the evolution of the specialized breeding habits of the honey guides, an African family of birds. Full geological details of the birth and growth of a volcano are given in a report on the Volcán de Paricutin in Mexico.

Directory of Scientific and Technical Libraries South of the Sahara

The Scientific Council for Africa South of the Sahara has issued as Publication No. 8 a "Directory of Scientific and Technical Libraries in Africa South of the Sahara" (pp. 61; P.O. Box 21, Kikuyu, Kenya, 1953; 2*s*. 6*d*.). This represents the first stage of work projected by the Council on scientific and technical library services in Africa. Both general and special libraries are included, and entries are arranged first alphabetically under the headings of metropolitan countries participating in the work of the Council, then regional groupings of territories, where applicable, and finally under separate territories. Under each regional or territorial heading the libraries or departments concerned are listed and numbered in alphabetical order, and the geographical and subject indexes refer to country and number. Although the bulk of the entries relate to government, university or institutional libraries, a few industrial libraries—for example, those of African Explosives and Chemical Industries, Ltd.—are included. The principal subjects covered, the number of volumes, pamphlets and current periodicals are indicated for each library. It is intended to follow the Directory with lists of periodical literature held by these libraries, where not already available, and, finally, to compile detailed catalogues for all the larger libraries.

Forest Research in India and Burma, 1948–49

Part 2 of "Forest Research in India, 1948–49" deals with reports for Burman and Indian Provinces (pp. 72. Delhi: Manager of Publications, 1952; Rs. 5 or 8*s*.) and is divided into four chapters as follows: sylviculture and working plans are dealt with for Assam, West Bengal, Bihar, Orissa, Bombay, Central Provinces and Berar, Burma, Coorg, Madras, Punjab and United Provinces; forest botany for Assam, West Bengal, Central Provinces and Berar, and Burma; forest entomology for Assam, Central Provinces and Berar, Burma and Punjab; utilization and economic research for Assam, West Bengal, Orissa, Bombay, Burma, Madras and United Provinces. An outstanding and serious problem faces Burma in the important branch of forest working plans. Up to the outbreak of the Second World War, Burma held her forests in high esteem and had working plans covering the greater part of the country, thus safeguarding the forests from over-exploitation. Many of these plans had been revised several times. It is impossible to attribute the present deplorable position entirely to the destruction of records during the War, although this claim is made. The real reason is that given: "Most divisional forest officers are new to the divisions and have no previous knowledge of their charges and are therefore not quite capable to cope with the revision of the plans until they know more about the division. The assistants are few and inexperienced to give much help in the compilation of the plans and most officers have new and inexperienced clerical staff".

A *Stauropteris* with two Megaspores

A Lower Carboniferous species of *Stauropteris*, *S. burntislandica*, is described as normally bearing two well-developed megaspores—a condition unknown elsewhere in the plant kingdom (K. R. Surange, *Phil. Trans. Roy. Soc.*, B, 237, No. 642, 73; 1952). The sporangium containing small spores which was already known is now recognized as being a microsporangium. The author considers that heterospory may be found in other species of this genus. The reconstruction of the frond, essentially a repeatedly dichotomizing branch system, suggests that it may have been supported on an underground stem. Critical specimens showing the attachment of the *Bensonites* fruits to small ultimate *Stauropteris* branchlets have been obtained. These spindle-shaped bodies, formerly recorded as *Bensonites*, are now known to be megasporangia, typically containing two well-developed megaspores. There are indications that a tetrad of young megaspores was initially present but that two of them had degenerated. The mode of spore liberation is still obscure. The author considers that *Stauropteris* can no longer be included among the primitive ferns: it deserves to be placed in a separate order of its own. Phylogenetically, it may have sprung from the common ancestor of the Psilophytales, together with the Zygopterideæ, but may have separated early from that group and evolved in the direction of the Pteridospermæ.

Experimental Taxonomy

In a survey of "Methods of the Experimental Ground in Relation to Taxonomy", Dr. W. B. Turrill (*Kew Bull.*, 3, 427; 1952) has considered the aims and procedures in experimental taxonomy. These are held to be essentially supplementary to the herbarium and other methods used by the taxonomist, and not a replacement of them. The advantages and limitations of the experimental approach, and the methods and principles to be adopted in it, are set out. Ecological and genetical studies, undertaken in the taxonomic interest, are naturally among the main features of this work. Though experimental taxonomy is unavoidably of a long-range character, it offers a wide and interesting field for discovery and introduces students to a new and dynamic aspect of taxonomy.

Earthquakes in New Zealand during 1951

Some 291 earthquake epicentres for earthquakes which happened in New Zealand during 1951 have been catalogued by R. C. Hayes and recently published (*N.Z. J. Sci. Tech.*, B, 34, No. 4; 1953). The general distribution followed a familiar pattern. Most of the earthquakes had epicentres in the South Island north of latitude 43° S., in the straits between the Islands and in North Island except the portion north of latitude 38° S. and west of longitude 176° E., where none occurred. The only epicentres south of latitude 43° S. were three immediately to the west of Dunedin, two near lat. 45° S., long. 169° E., and one at sea near lat. 44° S., long. 167·3° E. Eight shocks during the year were felt with intensity 6 or greater on the Modified Mercalli Scale, and nine shocks attained an instrumental magnitude of 6 or greater. Only three of these earthquakes had intensity and magnitude both greater than 6, these being as follows: February 10d. 03h. 27·9m., G.M.T., lat. 40·2° S., long. 177·0° E., instr. mag. 6·25–6·5, Mod. Merc. intensity 6; April 23d. 06h. 50·3m. G.M.T., lat. 37·8° S., long. 178·2° E., instr. mag. 6·75, Mod. Merc. intensity 7 (?); June 24d. 04h. 41·8m., G.M.T., lat. 39·4° S., long. 176·2° E., instr. mag. 6·25, Mod. Merc. intensity 6–7. Isoseismal lines are drawn for "two of the most important earthquakes of the year". One of these was that of June 24, mentioned above, and the other occurred on January 10d. 19h. 15m., G.M.T., lat. 42·8° S., long. 173·2° E., instr. mag. 5·6 *ca.*, Mod. Merc. intensity 7. The January earthquake was felt in Christchurch with Modified Mercalli intensity 4, and the June earthquake was felt in Wellington with Modified Mercalli intensity 5.

Colonial Service: Recent Appointments

THE following appointments have recently been made in the Colonial Service: J. H. Gisborne (botanist, Agricultural Department, Nigeria), principal agricultural officer, Nigeria; F. J. Harper (senior agricultural officer, Nigeria), deputy director of agriculture, Sarawak; C. A. Thorold (plant pathologist, Nigeria), principal research officer, Nigeria; J. M. Watson (senior agricultural officer, Uganda), director of agriculture and veterinary services, Somaliland Protectorate; J. M. S. Usher-Wilson (senior agricultural officer, Nigeria), principal agricultural officer, Nigeria; W. B. Collins, J. Gordon, M. T. Horwood, D. A. Lane and J. M. Ramsay (assistant conservators of forests, Gold Coast), senior assistant conservators of forests, Gold Coast; R. M. Harley and C. J. Taylor (senior assistant conservators of forests, Gold Coast), conservators of forests, Gold Coast; D. W. Powell (geologist, Water Development Department, Tanganyika), geologist, Uganda; R. G. Seal (geologist, British Guiana), geologist, Uganda; E. W. Temple-Boreham (game ranger, Kenya), senior game ranger, Kenya; P. O. M. Hosten (land settlement supervisor, Trinidad), agricultural officer (land settlement), Trinidad; T. A. M. Nash (chief entomologist, West Africa Inter-Territorial Research), deputy director, West Africa Inter-Territorial Research; F. W. Will (livestock officer, Nyasaland), livestock marketing officer, Veterinary Department, Nyasaland; W. D. Ware-Austin, agricultural officer, Kenya; I. MacI. Macfarlane, veterinary officer, Nigeria; H. C. Hodgson, pyrethrum chemist, Kenya; Dr. P. J. Mullaney, chemical pathologist, Barbados; J. Tarala, veterinary officer, Kenya.

University of London

THE following announcements have recently been made from the University of London. The titles of professor emeritus in the University have been conferred on the following on their retirement from their respective chairs: Prof. W. G. Bickley, mathematics at the Imperial College of Science and Technology; Prof. William Brown, plant pathology at the Imperial College of Science and Technology; Prof. J. W. Munro, zoology and applied entomology at the Imperial College of Science and Technology; Prof. H. R. Robinson, physics at Queen Mary College; and Prof. Gilbert Stead, physics at Guy's Hospital Medical School. The following have been appointed to University readerships, all tenable at the Imperial College of Science and Technology, in the subjects as indicated: J. R. Ashby (civil engineering), Dr. C. C. Butler (physics) and Dr. R. M. Goody (meteorology). The title of reader in mathematics in the University has been conferred on Dr. D. B. Scott, in respect of the post held by him at King's College.

The Oldest Agricultural Research Institute

DR. W. LANE-PETTER points out that the description of Rothamsted in the leading article in *Nature* of July 18 as "the oldest agricultural research institute in the world" might be misunderstood, as Boussingault set up an experimental farm at Bechelbronn in 1836, seven years before Rothamsted was founded. Boussingault's farm, however, was abandoned after the Franco-German War in 1870, and Rothamsted can thus now claim to be the oldest agricultural research institute.

Announcements

THE British Standards Institution is moving from its present premises, and, as from August 17, its new address will be No. 2 Park Street, London, W.1 (Telephone, MAYfair 9000).

THE Bibliography of Scientific Publications of South Asia, No. 7, covering India, Burma and Ceylon, for January–June 1952 (pp. 171. New Delhi: Unesco South Asia Science Co-operation Office, 1953; n.p.) includes a supplementary catalogue of scientific publications in South Asia and a supplementary list of new periodicals. The arrangement of the entries is the same as in previous issues of the bibliography, and the present issue includes some 3,500 entries.

THE Year Book for 1953 of the Library Association (pp. 528. London: Library Association, 1953. 21*s*., or 15*s*. to members) is the usual convenient reference work including, besides the charter and by-laws of the Association, lists of officers and committees, members and professional register and the syllabus of examination, and a list of library associations of the world. There are also lists of publications of the Association, a list of jubilees and centenaries and a graded list of text-books and works of reference, now running to sixty-seven pages.

A LIST OF PUBLICATIONS of the Commonwealth Scientific and Industrial Research Organization, Australia, to December 1952, issued by the Commonwealth Council for Scientific and Industrial Research (pp. 32; Melbourne, 1953), lists serially the handbooks and monographs, journals, bulletins, pamphlets, circulars, divisional publications, etc., of the Council and its predecessors, of the Institute of Science and Industry and of the Advisory Council of Science and Industry. Those out of print are indicated, and, unless otherwise mentioned, copies of the publications listed are obtainable from the Secretary (General Administration), Commonwealth Scientific and Industrial Research Organization, 314 Albert Street, East Melbourne, C.2, Victoria, Australia.

Erratum. In the communication by Mr. B. Lincoln on "Elastic Deformation and the Laws of Friction", published in *Nature* of July 25, p. 169, the sentence beginning at the sixth line of the second paragraph should read: "The assumption that $n > 0 \cdot 67$ indicates some degree of plastic deformation may, however, be unjustified, . . .".

ADAPTATION IN MICRO-ORGANISMS

A SYMPOSIUM on "Adaptation in Micro-organisms" was held by the Society for General Microbiology during April 14–15 at the Royal Institution, London. The papers of the contributors had been circulated to members of the Society beforehand, and the symposium was arranged in the form of discussions of each paper following a brief introduction by the author.

Dr. R. Y. Stanier (University of California), who introduced the symposium, defined two types of adaptive phenomena. Evolutionary adaptation involves selection of an organism possessing suitable characteristics which enable it to multiply in a specific environment and to survive natural environmental changes. In physiological adaptation, cells of a population adjust themselves directly to meet a sudden change in the environment. Classical genetical adaptation of micro-organisms is restricted, he suggested, by the predominance of haplophase and "a spotty distribution of sexuality", although this latter characteristic was questioned in discussion by Dr. Muriel Robertson and Dr. G. Pontecorvo. Yet micro-organisms live in micro-environments which are subject to rapid fluctuations—the environments are "discontinuous in time". We might expect, therefore, physiological adaptation to be of considerable importance among microbial populations.

Dr. A. C. R. Dean and Sir Cyril Hinshelwood (University of Oxford) discussed further the distinction between adaptations which could be attributed to mutant selection and those which are based upon changes in the whole population. They have evidence that the ability of *Bacterium lactis aerogenes* (*Aerobacter aerogenes*) to grow in the presence of proflavine or chloramphenicol is not due to selection of drug-resistant strains. For example, cultures derived from colonies which have grown in the presence of high concentrations of proflavine show no greater resistance to proflavine than does the original culture which has never come in contact with the drug. Resistance has not been deeply impressed on the organism, neither has a mutant been selected. However, resistance which is not lost on growth in the absence of the drug may be impressed by continuous sub-culture in the presence of the drug. That this observation could be due to mutant selection seemed to Dr. Dean and Sir Cyril to be incompatible with the high reversion-rate which has to be assumed to account for the stability of the non-resistant culture. They concluded that the selection of mutant strains might not play a big part in the development of drug resistance.

Dr. A. W. Ravin (Columbia University, New York) discussed the occurrence in populations of *Aerobacter aerogenes* of cells with varying ability to utilize citrate and other intermediates of the tricarboxylic acid cycle. Normally, growth of the organism on these compounds occurs after a lag during which nearly all the population develop the ability to utilize these acids. This ability is lost on sub-culture on glucose, but is regained on further sub-culture on citrate. In any culture of the organism, however, Dr. Ravin has shown that there are some mutant cells which do not utilize citrate; their relative number is increased by irradiation with ultra-violet light. Cultures derived from such cells show a permanent loss of ability to utilize citrate. It was pointed out that heterogeneous populations probably occur very frequently in microbiology and may complicate studies of adaptation. In discussion Dr. Monod suggested that such heterogeneity of a population might be due to some cells having, and others lacking, energy reserves or intermediates of some kind necessary for synthesis of the adaptive enzyme required for growth. Later in the symposium, Dr. M. R. Pollock followed up this point of an overall shortage of some such compound, speaking of the "quantum mechanics of bacteria".

Dr. Ravin also introduced the paper of Dr. P. P. Slonimski (Laboratoire de Génétique du Centre National de la Recherche Scientifique, Paris), who was unable to be present. Dr. Slonimski's work on the effect of acriflavine on the formation of cytochrome oxidase by yeast provides an interesting example of a specific relation between the hereditary and non-hereditary nature of formation of an enzyme system. Yeast cells which have been grown in the presence of acriflavine give rise to small colonies. Cells derived from such colonies are deficient in cytochrome oxidase and retain this characteristic indefinitely during vegetative reproduction. Acriflavine also specifically inhibits the adaptive formation of cytochrome oxidase and related enzymes in anaerobically grown yeast when the cells are exposed to oxygen. The experimental results indicate that acriflavine inhibits some specific reaction which governs both the hereditary and the adaptive mechanisms of respiratory enzyme formation.

Other papers on the first day dealt with the mechanism of synthesis of adaptive enzymes. The biosynthesis of adaptive, as opposed to constitutive, enzymes can be studied directly, and it seems reasonable to believe that information derived from such studies should be applicable to the formation of constitutive enzymes and of proteins in general.

Dr. M. R. Pollock (Institut Pasteur, Paris, and National Institute for Medical Research, London) spoke of the difficulty of studying adaptive enzyme synthesis as an isolated phenomenon, since it requires such close integration of energy-yielding reactions and reactions yielding intermediates in the synthetic chain. The adaptive formation of penicillinase by *Bacillus cereus* has been investigated in cells during the logarithmic phase of growth when metabolism has reached a steady state. Brief exposure of the cells to penicillin at this stage induces formation of the enzyme, which continues after removal of the drug. Quantitative considerations indicate that the ratio of molecules of penicillin fixed to molecules of penicillinase formed is very small, suggesting a catalytic role for penicillin, probably as a complex with a cell component. Dr. Pollock visualized a cyclical chain of reactions primed by an inducer-cell component complex and leading to the formation of the enzyme.

The role of the inducer in enzyme synthesis was further discussed by Dr. M. Cohn and Dr. J. Monod (Institut Pasteur, Paris). They suggested that induction is necessary in the formation of both constitutive and adaptive enzymes. In the former case the specific inducer may be a product of the metabolism of normal cells, whereas an external inducer is required for the creation of an adaptive system. It is postulated that either external or internal inducers give rise to organizers which are concerned in the arrangement of amino-acids into enzyme proteins. Thiophenol-β-galactoside is apparently a competitive antagonist of induced β-galactosidase synthesis in *Bacterium coli*, and studies have been commenced in an effort to find compounds which may act as specific antagonists of inducers of constitutive enzymes.

Dr. S. Spiegelman and Dr. H. O. Halvorson (University of Illinois) have investigated the utilization of free amino-acids in cells of *Saccharomyces cerevisiae* during the formation of the adaptive system maltozymase. Enzyme synthesis occurs at the expense of the free amino-acids within the cells and cannot occur if the cells contain no free amino-acids. Their results suggest that the first stable (an important qualification which was sometimes overlooked in discussion) intermediates in enzyme formation must be of considerable complexity.

Prof. R. Knox (Guy's Hospital Medical School, London) emphasized differential temperature sensitivity as a means of distinguishing between adaptive processes and growth not involving such mechanisms. The formation of adaptive enzymes appears to be more sensitive to temperature change than is cell proliferation. For example, the sensitivity of *Bacillus cereus* to penicillin is increased at temperatures which suppress the adaptive formation of penicillinase, but which do not affect growth in the absence of the drug. The sensitivity of adaptive changes to heat may be of importance in chemotherapy; there is already some evidence that isoniazide is more effective against tubercular infection in animals with abnormally high body temperatures.

On the second day Dr. E. P. Abraham (University of Oxford) ably introduced a discussion on drug resistance among micro-organisms. The development of resistance has most frequently been observed in cultures which have been in contact with the drug. In some cases selection of a spontaneous mutant may occur; in others, growth in the presence of the drug seems to be due to adaptive changes in most of the cells of the population. Dr. Abraham considered it very difficult to determine which type of change has occurred and found the replica technique of Lederberg and Lederberg alone convincing in its ability to make this distinction. Finally, he pointed out that it is scarcely surprising that so little is known about the factors causing drug resistance, when the modes of action of so few drugs have been elucidated.

It was evident from the following discussions that organisms differ greatly in their ability to tolerate any one drug, and that even in a single strain different types of resistant variant may be isolated in a single experiment.

This was particularly emphasized by Dr. Mary Barber (St. Thomas's Hospital Medical School, London), who showed slides illustrating the wide variation, both heritable and non-heritable, among strains of *Staphylococcus aureus* which can grow in the presence of antibiotics.

Dr. D. A. Mitchison (Postgraduate Medical School, London) discussed the variations in resistance found among organisms isolated from hosts after streptomycin and isoniazid therapy. Changes in the population of tubercle bacilli have been noted in cases treated with streptomycin; drug-resistant strains may be replaced by sensitive strains on withdrawal of the drug. He stressed the importance of this phenomenon and also the relation of resistance to virulence and viability in medicine and public health.

The concluding papers dealt with a variety of micro-organisms ranging in size from bacteriophage to *Paramecia*. Dr. L. F. Hewitt (Serum Research Institute, Surrey) discussed the control that bacteriophages may exert over evolution in bacteria. They are known to act first by selection of phage-resistant strains due to lysis of phage-sensitive cells, and, secondly, by the actual transmission of genetic characters of one cell to another through an infecting phage entering a cell without lysis occurring. In the second case detection is difficult since it depends upon contact of the phages with organisms sensitive to lysis by them. In addition, bacteriophages are themselves capable of adaptation. Thus from one phage active against a particular strain of *Corynebacterium diphtheriae*, phages can be obtained which lyse cells of different serological type.

Many of the arguments concerning the nature of changes in bacterial populations have centred on the question of whether or not a mutation has occurred. Dr. G. H. Beale (University of Edinburgh) pointed out that it is impossible to provide unequivocal answers to such questions since controlled breeding experiments cannot be carried out with bacteria. In *Paramecium*, however, such experiments can be performed. He discussed several types of adaptation in this organism, all of which arose during asexual reproduction. In the case of variation in antigenic structure, it was shown that a change in the cytoplasm had occurred rather than a gene mutation followed by selection. Similar phenomena probably account for other adaptations studied in this organism. Nevertheless, the ability of a strain to adapt to given conditions is genetically controlled.

Dr. L. F. L. Clegg (National Institute for Research in Dairying, Shinfield) and Dr. S. E. Jacobs (Imperial College of Science and Technology, London) described work with thermophilic organisms which grow optimally at temperatures above 50° C. Though most thermophiles can adapt themselves to grow at lower temperatures, there are very few examples of adaptation of a mesophilic organism to the thermophilic mode of life. Dr. M. R. Pollock suggested that the inability of some thermophiles to grow at lower temperatures might reside in changes in the equilibrium of reactions concerned in synthetic processes in the cell.

Prof. W. Brown and Dr. R. K. S. Wood (Imperial College of Science and Technology, London) dealt in particular with the adaptation of fungi to their natural habitat. Little is known of the physiological processes which enable them to flourish in the chosen conditions. The life-cycle of fungi is a very important factor in their ability to survive wide environmental fluctuations. The vegetative stage gives rise quickly to conidia, which can germinate immediately when favourable conditions arise. Under unfavourable conditions, fungi can carry on sexual reproduction which yields long-lived resistant spores.

Perhaps the most striking impression gained from the symposium as a whole was the very considerable measure of agreement over the respective parts played by single cell and selective adaptation in microbial growth. Much of the lively discussion appeared to arise through the inability of chemists, bacteriologists and geneticists to appreciate fully one another's modes of expressing their conclusions. It was also clear that even a surface understanding of the closer physiological relationship between the two mechanisms of adaptation must await further experimental work.

SMITHSONIAN INSTITUTION

ANNUAL REPORT FOR 1951–52

THE report of the Smithsonian Institution for the year ended June 30, 1952*, includes the secretary's report, to which are appended departmental reports on, *inter alia*, the United States National Museum, the Bureau of American Ethnology, the International Exchange Service, the Astrophysical Observatory, the National Zoological Park, the National Air Museum, the Canal Zone Biological Area and the Institution's library, and the report of the executive committee of the Board of Regents. The secretary's report is the last from Dr. Alexander Wetmore, who retired from administrative duties at his own request, to continue scientific work as research associate of the Institution, and was succeeded at the beginning of this year by Dr. L. Carmichael (see *Nature*, 169, 952; 1952).

In his final report, Dr. Wetmore points out that, although the pay-roll of the Institution has more than doubled during the past twenty years, the hours of service per week have decreased (from 20,592 man-hours in 1942 to 20,200 hours in 1952, with a greatly increased work load). Unless this situation is speedily remedied, the Institution will have to curtail its duties or its services. All available space is now fully utilized; but additional buildings for the United States National Museum and National Air Museum, for the collections in art, and for research work in natural history and other fields are essential, and a substantial increase in endowments is required for this purpose as well as for research and publications and general maintenance. Of the present appropriation of 2·5 million dollars, nearly 900,000 dollars goes on maintenance and operation of buildings, nearly 800,000 dollars on the National Museum, 319,000 dollars on general services, 177,000 dollars on the National Air Museum and 116,000 dollars on the Astrophysical Observatory. During the year the Mary Vaux Walcott Fund for Publications in Botany, amounting to 60,000 dollars, was established: publications issued under this Fund will be chiefly technical and will relate to researches of the United States National Herbarium.

More than 607,000 specimens were received and distributed among the six departments of the United States National Museum, which also issued twenty-seven publications during the year. Field-work was conducted on the distribution and variation of the bird-life of the Republic of Panama, on the ecology and on the life-history of freshwater fishes in the streams draining the mountain and Piedmont plateau sections of the Atlantic slope from Virginia to Georgia and Alabama. The ornithological survey of Columbia was continued and also the study of mammalian and other hosts involved in the transmission of scrub typhus in the vicinity of Mount Kinabalu, British North Borneo, while a field study was made of the relation of the Bromeliaceæ to malarial control in eastern Brazil.

The bulk of the report on the Bureau of American Ethnology is occupied by a report on the River Basin Surveys, prepared by Dr. F. H. H. Roberts, director of the Surveys. Since the beginning of this project seven years ago, 3,105 archæological sites have been located and recorded, and, of these, 578 have been recommended by excavation or limited testing. The excavation work during the year covered thirteen reservoir areas in eleven States, with twenty-two excavating parties in the field. Besides this, the Bureau's staff continued systematic research on Mexican and Panamanian archæology, on the Eskimo and archæology of Cornwallis Island in the Canadian Arctic, on the Maya language, on the Iroquois and on Meso-American archæology. During the year the activities of the Institute of Social Anthropology were integrated with those of the Institute of Inter-American Affairs under an arrangement by which the Smithsonian anthropologists will be available for programme analyses of technical aid projects.

The number of packages of government, scientific and literary publications handled during the year by the International Exchange Service totalled 1,001,614, weighing 825,627 lb., consignments being made to all countries except China and Rumania. In exchange for similar publications of other countries, sixty-two full and forty-two partial sets of United States official publications were sent abroad, as well as eighty-seven copies of the Federal Register and ninety-four of the Congressional Record. Lists of depositories are given in the report. Visitors to the National Zoological Park numbered about 3·3 millions, and the 2,675 animals included fourteen species not previously exhibited. A list of animals in the collection at June 30, 1952, is given.

At the Astrophysical Observatory solar-radiation studies continued at the high-altitude stations at Table Mountain, California, and at Montezuma, Chile, while five silver-disk pyrheliometers were constructed and furnished at cost to institutions in France, Finland, Central Africa, Greece and Rhode Island. The study at Table Mountain on the ozone content of the upper atmosphere from daily bolographic records continued, and, in the Division of Radiation and Organisms, studies on bean seedlings indicate that photomaturation responses are not directly concerned either with chlorophyll synthesis or photosynthesis, but are due to a regulatory mechanism associated with a pigment having maximum absorption in the far red. Clear evidence was also obtained that the synthesis of anthocyanin is a photochemical response, separate and distinct from photosynthesis. Work on the effect of growth regulators on the uptake of nutrient salts by bean seedlings continued, and it appears that the reduced uptake patterns are chiefly related to decreased growth of the plants treated with the growth regulator.

The principal purpose of the (Panama) Canal Zone Biological Area is to provide a safe tropical environment for research, and during the year 602 visitors went to the Barro Colorado Island station, of whom forty-eight were men of science who used the facilities of the island for biological studies. One such study, by Dr. E. Eisenmann, resulted during the year in the publication by the Institution of the "Annotated List of Birds of Barro Colorado Island, Panama Canal Zone", listing 306 species; and since the time when the list was given in the 1950 report, seven species of vertebrate animals other than birds have been added to the known fauna of the area, bringing the total of vertebrate forms to 486. During the year the National Museum Library was merged physically with the general library and all major library functions were consolidated and housed in the Natural History Building. The library received 60,512 publications during the year, mostly by gifts and exchanges. A list of Smithsonian publications during the year is appended, and these include, besides the sixth revised edition of the Smithsonian Meteorological Tables and the Smithsonian Logarithmic Tables, E. A. Goldman's "Biological Investigations in Mexico", A. H. and L. F. Clarke's "The Butterflies of Virginia" and F. Rasetti's "Middle Cambrian Stratigraphy and Faunas of the Canadian Rocky Mountains".

---

* Smithsonian Institution. Report of the Secretary and Financial Report of the Executive Committee of the Board of Regents for the Year ended June 30, 1952. (Publication 4102.) Pp. 175. (Washington, D.C.: Govt. Printing Office, 1953.)

UNIVERSITY AFFAIRS IN GREAT BRITAIN, 1951–52

THE "Returns from Universities and University Colleges in receipt of Treasury Grant for the Academic Year 1951–52"*, issued by the University Grants Committee, show a further decline of 1,856 in the number of full-time students—to 83,458, compared with 85,314 in 1950–51 and 85,421 in 1949–50. In English universities, full-time men students decreased by 724, but women students increased by 128; for Wales the corresponding figures were 276 and 6, while for Scotland there were 861 fewer men and 129 fewer women. Overseas students from within the British Commonwealth increased by 264 to 3,921 full-time and 1,636 part-time students, and students from foreign countries by 137 to 3,039 full-time and 1,320 part-time students. While the reduction in numbers of full-time students was distributed fairly generally over all faculties, except dentistry, which increased by four, from 2,885 in 1950–51 to 2,889 in 1951–52, it will be noted that although the largest decrease (852) was in arts students (to 35,936), those in pure science decreased by 115 to 17,053, of technology by 376 to 10,215, of medicine by 291 to 13,910, of agriculture by 188 to 2,418, and of veterinary science by 38 to 1,037. Full-time advanced students of pure science decreased by 35 to 2,858, of medicine by 27 to 965, of agriculture by 4 to 274, and of veterinary science by 3 to 10. On the other hand, full-time advanced students of technology increased by 98 to 1,105, of dentistry by 20 to 42, and of arts by 17 to 3,314. Of the full-time students, 66,409 were reading for a first degree, 5,505 for a first diploma, and 11,544 were engaged in research or other advanced work, the corresponding figures for 1950–51 being 67,743, 6,244 and 11,327, respectively.

The proportion of assisted students was practically unchanged (72·4 per cent compared with 72·5 per cent in 1950–51); but although the figure for England as a whole remained unchanged, decreases at Oxford (from 75·7 to 71·7 per cent) and at Cambridge (from 74·3 to 67·8 per cent) were more than offset by increases at London (from 65·9 to 67·7 per cent) and at other universities (from 77·9 to 79·5 per cent). In Wales the percentage of assisted students increased from 85·9 to 88·3; but in Scotland there was a decrease from 63·1 to 61·6. The dependence on Parliamentary grants again increased, and now represents 66·5 per cent of recurrent income, compared with 64·9 per cent in 1950–51, only 14·8 per cent coming from fees, compared with 16·6 per cent in 1950–51, 5·2 per cent from endowments, 4·1 per cent from local authority grants and 1·9 per cent from donations and subscriptions, compared with 5·5 per cent, 4·3 per cent and 1·8 per cent, respectively, in 1950–51. The ratio of staff to students again increased, the full-time teaching staff being now 8,952 compared with 8,603 in 1950–51 and 7,930 in 1949–50. The increase was distributed fairly generally over most grades—professors, 43; readers, assistant professors and independent lecturers, 8; senior lecturers, 71; lecturers, 222—but assistant lecturers and demonstrators decreased by 58 to 1,537. Classified figures are included for the 2,454 full-time teaching staff of the University of London and for the staffs of its libraries, and the analysis of expenditure of the institutions of the University of London is now accompanied by those of the Universities of Durham and Wales.

Of the full-time students, 63,584 were in England, 4,863 in Wales and 15,011 in Scotland. Of these, 15,084 were at Oxford and Cambridge, 18,312 at London, and 30,188 at other English universities and colleges. Changes at the individual universities and colleges were usually slight, only Cambridge and North Staffordshire University College (157 to 300) showing increases of more than a hundred students, and only the universities of Oxford, Liverpool and Manchester and the Manchester College of Technology decreases of more than a hundred. The proportion of full-time students residing in colleges and halls of residence increased to 25·9 per cent; the proportion of men in residence was 21·2 per cent and of women 41·2 per cent, while 33,005 students (39·6 per cent) were in lodgings and 28,828 (34·5 per cent) at home. Of the 22,414 students admitted for the first time in 1951–52 (an increase of 191 on 1950–51), 20,567 were reading for a first degree and 1,847 for a first diploma, and of those reading for a first degree, 1,926 were less than eighteen years of age and 11,542 were nineteen or more. There was no significant change in the distribution of full-time students compared with 1949–50 or 1950–51. Arts students again represented 43·1 per cent of the total, those in pure science 20·4, in medicine 16·7, in technology 12·4, in dentistry 12·5, in agriculture 2·9, and in veterinary science 1·2 per cent. While the proportion of full-time advanced students of technology increased to 12·9 per cent compared with 11·8 per cent in 1950–51, there is no other sign in these returns of any response to the urgent call for more university-trained technologists, and although 25·8 per cent of full-time advanced students were working for a teacher's diploma, the contribution of the universities towards the supply of science teachers cannot be estimated from these returns. Of the full-time students, 36,745 out of 49,275 men, and 10,160 out of 14,309 women in England, were receiving assistance in the way of scholarships, exhibitions or other awards from public or private funds; for Wales, the corresponding figures are 3,154 out of 3,546 men, and 1,142 out of 1,317 women; and for Scotland, 7,275 out of 11,149 men, and 1,976 out of 3,862 women. Of 63,970 full-time men students, 36·8 per cent were in arts, 21·5 per cent in pure science, 17·2 per cent in medicine and 15·7 per cent in technology; for the 19,488 women students the corresponding figures are 63·3, 17·0, 15·1 and 0·9 per cent. Medicine and dentistry claimed 51·1 per cent of the part-time advanced students, arts 33·0, technology 8·0, and pure science 7·2 per cent, compared with 44·6, 30·4, 9·6 and 8·7 per cent, respectively, in 1950–51.

The recurrent income of the universities and university colleges of Great Britain increased by

* University Grants Committee. Returns from Universities and University Colleges in receipt of Treasury Grant, Academic Year 1951–1952. (Cmd. 8847.) Pp. 44. (London: H.M. Stationery Office, 1953.) 2s. 6d. net.

£1,479,876 to £25,747,999, of which £17,126,993 was from Parliamentary grants, £3,807,440 from fees, £1,347,570 from endowments and £1,044,151 from grants from local authorities. Of the total income from public funds of £18,171,144 and £7,576,855 from other sources, the University of London received £5,484,932 from public and £2,146,915 from other sources; the University of Cambridge similarly received £1,141,350 and £1,161,231; for Oxford the corresponding figures are £1,010,283 and £684,469; for Manchester, £947,752 and £276,832; for Birmingham, £784,576 and £251,156; for Durham, £779,311 and £326,310; for Leeds, £766,052 and £266,472; for Liverpool, £719,115 and £233,220; for Bristol, £684,082 and £313,864; and for Sheffield, £497,520 and £156,079. No other English university or university college had an income exceeding half a million pounds. but all four universities in Scotland exceeded this figure: Aberdeen, with £432,750 from public and £137,453 from other sources; Edinburgh, with £840,906 and £354,792; Glasgow, with £894,950 and £349,042; and St. Andrews, including Dundee University College, with £413,400 and £112,640, respectively. The University of Wales, including the Welsh National School of Medicine, received £900,678 from public funds, and £320,893 from other sources.

Of the total expenditure of £26,132,122, an increase of £2,098,937 on the previous year, administration accounted for 8·8 per cent, departmental maintenance 69·3, maintenance of premises 11·4, and miscellaneous expenditure 9·5 per cent. Capital expenditure met from income amounted to £258,963 and allocations to reserves to £222,536; for 1950–51 these figures were £254,274 and £236,707, respectively. Departmental maintenance included salaries of teaching and research staff and payments for superannuation, the running costs of laboratories, lecture rooms, libraries and museums, and the supply of materials, apparatus, books, specimens, etc. Salaries and superannuation amounted to £12,542,994 compared with £11,895,971 in 1950–51; this represents 48 per cent of the total expenditure compared with 49·1 per cent in 1950–51, with a 4 per cent increase in full-time staff.

Library expenditure, excluding general maintenance of library buildings, etc., rates, heat, light, repairs, etc., amounted to £988,029, or 3·8 per cent of the total expenditure, compared with £891,385 and 3·7 per cent in 1950–51. Of this total, £527,238 was for salaries and wages, £202,567 on account of books, £118,702 on periodicals and £85,087 on bindings. The University of Oxford spent £27,160 on books, Cambridge £11,623 and Manchester £10,924, while a total of £53,730, including £7,478 on the Central Library, £4,787 at the London School of Economics, £5,713 at the School of Oriental and African Studies, and £6,425 at University College, was expended for this purpose in the schools and colleges of the University of London. Ten other universities, Birmingham (£6,574), Bristol (£5,689), Durham (£6,328), Leeds (£7,377), Liverpool (£8,110), Reading (£7,582), Aberdeen (£5,818), Edinburgh (£7,686), Glasgow (£9,326) and St. Andrews (£5,163), spent £5,000 or more on books; and London (£35,435), Oxford (£8,953), Cambridge (£8,641), Glasgow (£8,258) Edinburgh (£5,677) and Manchester (£5,193) spent a similar sum on periodicals. The University of Wales, including the Welsh National School of Medicine, spent £7,987 on books and £6,167 on periodicals.

DUTCH–NORWEGIAN JOINT ESTABLISHMENT FOR NUCLEAR ENERGY RESEARCH

THE Dutch–Norwegian co-operative effort in the field of atomic energy was established in April 1951, and its initial aim was the completion of the heavy-water uranium reactor, Joint Establishment Experimental Pile (JEEP), which was under construction at Kjeller, Norway. In order to further work in atomic energy in the two countries a joint commission consisting of three Norwegian and three Dutch members was set up, and the establishment at Kjeller was incorporated into a Dutch–Norwegian organization called the Joint Establishment for Nuclear Energy Research (J.E.N.E.R.). The first annual report of this organization has now been published*. Mr. Gunnar Randers, who was director of the Norwegian Institute for Atomic Energy (I.F.A.), was appointed director of the Joint Establishment, and, of the original members of the joint commission—Prof. S. Rosseland (chairman), O. Dahl, N. Stephenson, Prof. H. A. Kramers, Prof. C. J. Bakker and J. M. W. Milatz—Prof. Rosseland has since resigned as chairman and been succeeded by Prof. B. Trumpy, and Prof. Kramers has died. Since, however, the creation of the Joint Establishment was largely due to Prof. Kramers's initiative, it is most fitting that the annual report should include a photograph of him as frontispiece and commence with a brief appreciation of his high standing both in scientific circles and in the realm of international affairs.

The factual report is preceded by an extract from a lecture delivered by Mr. Randars on September 26, 1952, at the Technological Institute in Belgrade, Yugoslavia, in which he asserted that, though atomic energy research is undoubtedly an expensive item for small countries to undertake, it would be a mistake to believe that they have a choice as to whether they should undertake it or not. Small countries with large shipping interests—for example, Norway and the Netherlands—cannot afford to have the development of atomic ship propulsion come as a surprise to them, and he maintained that a group of small European nations might well, by joining forces, produce one of the best research and development teams for atomic energy.

Details are given, in the annual report, of the construction and operation of JEEP, which was started up on July 30, 1951. It has a graphite reflector of minimum thickness 70 cm. and uses uranium metal fuel rods contained in aluminium tubes. The reactor was run mostly with a charge of sixty-two rods (about 2·2 tons of uranium); but this is considerably below optimum. The maximum power-level so far developed is 100 kW. with a neutron flux at the centre of the pile of 3×10^{11} neutrons/cm.^{2} sec. The year under review was mainly a 'running-in' period for the pile, and therefore relatively little chemical work was required; but since the pile is well suited, from a technical point of view, for the production of radioisotopes, some research of a chemical nature has been started temporarily by the Isotope Section. It is hoped that when a regular isotope production is achieved at Kjeller, the import and distribution of isotopes from Britain, Canada and the United States, organized by the Joint Establishment, will be limited to isotopes and labelled compounds not available at Kjeller.

---

* Joint Establishment for Nuclear Energy Research. First Annual Report, 1951–52. Pp. 26. (J.E.N.E.R., Kjeller, pa. Lillestrøm, 1952.)

The work of the Physics Department was concentrated on the acquirement of a thorough theoretical understanding of the operation of the reactor and on the establishment of experimental facilities for research utilizing the neutron flux. Equipment available now includes a rotating velocity selector with spiral channels for the investigation of nuclear reaction cross-sections for thermal neutrons, a pile oscillator, a beta-spectrometer of the short-lens type with no iron core, two mass spectrometers and a ten-channel pulse-height analyser with a resolving time of about 20 µsec. Some preliminary discussions and investigations on new reactor types, with particular reference to ship propulsion reactors, are reported and this work is being continued. A health physicist was appointed to supervise the radiation monitoring programme, and the monitoring instruments which have been in use since the reactor started consist of permanent installations, mainly ionization chambers of the Chalk River type; semi-permanent monitors and portable monitors of the Harwell type; and personal monitoring equipment, dosimeters and films.

The report concludes with a statement of accounts of the Joint Establishment covering the period July 1, 1951–June 30, 1952; a list of personnel in the various departments; and details of the information service, together with references to the scientific articles published by members of the staff of the Establishment during the period under review.

CENSUS OF WOODLANDS IN GREAT BRITAIN

A MOST interesting report on the census of woodlands in Great Britain has been issued by the Forestry Commission*. The report is based on a comprehensive stocktaking, and this greatly amplifies the information published in 1951 in summary form. The present census was carried out between January 1947 and June 1949, no fewer than 308,000 tabular reports and maps being submitted by parties of trained surveyors. In the report the methods upon which the material collected was classified are detailed. The woodlands are divided into coniferous high forest, broad-leaved high forest, coppice and coppice with standards, scrub, devastated woods and felled woodland. The distribution of the woods will probably cause surprise to many. The counties with the largest woodland areas are: Inverness (212,616 acres), Yorkshire, Hampshire, Perth, Aberdeen, Sussex, Argyll, Kent and Devonshire; while Montgomery has more than any other county in Wales. All counties have some woodland—London, with 639 acres, or 0·9 per cent of its land area, is actually more densely wooded than Caithness.

The data given are separated for the Forestry Commission and private owner, respectively. The total area of woodland in Britain (excluding woodlands less than 5 acres in extent) at September 30, 1947, was 3,448,362 acres, or 6·1 per cent of the land surface of Britain, or only 71 acres of woodland to every 1,000 people. It is stated that Norway has 23·8 per cent of its land surface under trees, Belgium 18·2 per cent, and Denmark 9·3 per cent. As is well known, Britain has the lowest percentages of woodland compared with its land area to be found in Western Europe, excepting Ireland and Holland. The comparison is somewhat misleading. Britain is a small island, densely populated and highly industrialized. Timber is essential to these industries; but foresters and agriculturists realize that all land which can produce crops or feed stock must be utilized by the latter. This of necessity sets the limit to the future area of woodlands; in addition, areas for housebuilding and works have to be eliminated. In each county this matter is now under consideration between those concerned with development and extension of agricultural and forest areas.

The report states that 1,309,569 acres of the total area of woodland were classified in the census as scrub, devastated or felled areas, largely as the result of overfelling during the two World Wars. This figure, says the report, shows the amount of rehabilitation work necessary to restock these areas. There is some difference of opinion upon one type of woodland classified by the Commission as 'scrub'. There are considerable numbers of poor coppice areas in England so classified, and it is true that the coppice is at present in a poor condition. But this is due to the fact that, when the coppice value decreased, the owners failed to continue to replace the old stools as had been done periodically in the past from the time the area had been treated as coppice.

JOURNAL OF EMBRYOLOGY AND EXPERIMENTAL MORPHOLOGY

THE first part of a new quarterly journal, the *Journal of Embryology and Experimental Morphology*, devoted to animal morphogenesis has recently appeared*. Its object is to act as a forum for workers mainly interested in developmental processes to be found in animals at any stage of their life-history. Research work to be published in this new journal will include descriptive, experimental, chemical and physiological embryology, regeneration and healing, developmental changes involved in functional adaptation, growth, ageing, and other aspects of late morphogenesis. Studies of gametes and gametogenesis will be considered for publication, provided they are not primarily of a cytological nature; similarly, work on the physiology of reproduction will be accepted provided it does not more appropriately fall within the scope of any other specialized journal. Aspects of protozoology will also be considered which have a bearing on morphogenesis. Papers on developmental processes in plants will receive favourable consideration, too, if they in any way assist in clarifying zoological aspects of morphogenesis.

The new journal will concentrate mainly on finished pieces of research. This means that the papers published will contain sufficient data, tables and illustrations to make clear the authors' results and conclusions. Preliminary reports and theses, therefore, will not be favourably considered for publication; neither will very long papers. It is hoped, nevertheless, when space permits, to publish theoretical and review papers.

---

* *Journal of Embryology and Experimental Morphology*. (Oxford University Press, Amen House, London, E.C.4.) £4 4s. yearly; 25s. separate issue.

Contributions may be in English, French or German.

Such a journal is to be welcomed, especially since a strong editorial board of zoologists, anatomists and embryologists has been appointed. It will no doubt relieve congestion in other journals, and will prove invaluable as a platform for discussion, especially among those scientific research workers interested in the rapidly advancing field of morphogenesis—biological, medical, veterinary, agricultural and so forth. British members of the editorial board include such authorities as M. Abercrombie, G. R. de Beer, J. D. Boyd, F. W. R. Brambell, Honor B. Fell, W. J. Hamilton, Sidnie M. Manton, P. B. Medawar, D. R. Newth, C. H. Waddington, J. Z. Young and S. Zuckerman. Other countries are represented on the board by the following: J. Brachet, A. Dalcq, J. Pasteels (Belgium); E. Fauré-Fremiet, Et. C. Wolff (France); J. Holtfreter (United States); S. Hörstadius (Sweden); F. E. Lehmann (Switzerland); Chr. P. Raven and M. W. Woerdeman (Holland); A. Stefanelli (Italy); S. Toivonen (Finland).

Papers in the first (March 1953) issue, which follow a foreword written by A. M. Dalcq in the form of an essay on development, are: J. Pasteels: "Les effets de la centrifugation sur la blastula et la jeune gastrula des Amphibiens. (1) Mécanisme de la formation des organes secondaires aux dépens de l'ectoblaste"; R. M. Clayton: "Distribution of Antigens in the Developing Newt Embryo"; H. V. Brøndsted: "Rate of Regeneration in Planarians after Starvation"; A. and H. V. Brøndsted: "The Acceleration of Regeneration in Starved Planarians by Ribonucleic Acid"; Et. Wolff, K. Haffen, M. Kieny and Em. Wolff: "Essais de cultures *in vitro* d'organes embryonnaires en milieux synthétiques"; J. C. van de Kamer and A. J. Schuurmans: "Development and Structure of the Saccus Vasculosus of *Scylliorhinus caniculus* (L.)".

The editor of the *Journal of Embryology and Experimental Morphogenesis* is Michael Abercrombie, Department of Anatomy, University College, Gower Street, London, W.C.1, to whom all editorial communications should be sent.

ATMOSPHERIC OZONE AND THE UPPER-AIR CONDITIONS

THE amount of ozone in the atmosphere is very small, amounting to a layer less than 3 mm. thick at normal temperature and pressure. The ozone is nearly all in the stratosphere at heights between 20 and 40 km. and is of great importance as it absorbs almost all the solar ultra-violet radiation. Dobson showed in 1929 that over Britain the total amount of ozone changed with the surface pressure distribution; the ozone amount was found to be high on the western sides of depressions and low over anticyclones. This relation did not hold everywhere, and it was suggested that the true connexion was with the state of the atmosphere at high levels rather than that near the ground.

The latest researches into the subject are clearly described by Sir Charles Normand in his 1952 presidential address to the Royal Meteorological Society, which has now been published (*Quart. J. Roy. Met. Soc.*, 79, No. 339, 39; 1953). Observing at Oxford with the Dobson spectrophotometer, which permits observations of ozone amount to be made even when the sky is overcast with low cloud, he has found a close inverse correlation between ozone amount and the height of the 300-mb. isobaric surface, the thickness of the layer between 500 and 300 mb., and the height of the top of the troposphere—the tropopause. The connexion between them and ozone amount is very close, extending to variations taking less than a day to complete.

Besides reporting the result, Sir Charles discusses the origin. It was at one time thought that the relation between ozone and surface pressure distribution is due to horizontal motion of stratospheric air of high or low ozone content; but, though this may well be important during spring, when ozone increases from south to north, it cannot play a significant part during autumn, when there is very little latitudinal variation of ozone. Sir Charles sees the main reason for the relation between ozone amount and the meteorology of the upper troposphere in vertical motion in the stratosphere associated with rising or falling tropopause. As nearly all the ozone is in the stratosphere, it is clear that, provided formation and dissociation of ozone are sufficiently slow, convergence will bring about an increase in the total ozone content in a vertical column and divergence a decrease. Below 35 km. the mass of ozone in a given mass of air (ozone mixing ratio) changes very slowly, and there is convergence in the stratosphere when the tropopause sinks.

Using available information on the vertical distribution of ozone, Sir Charles shows quantitatively that this explanation is reasonable. He looks forward to more accurate information in future both on the vertical and horizontal distributions of ozone which will make the result more definite. This information is expected from the observations of a network of Dobson spectrophotometers now being set up from Spitzbergen to the Azores and Spain under the auspices of the Ozone Commission of the International Union for Geodesy and Geophysics.

DETERMINATION OF THE POSITION OF A RADIO STAR

A PAPER entitled "The Determination of the Position of a Radio Star" by F. G. Smith (*Mon. Not. Roy. Astro. Soc.*, 112, 5; 1952), describing work carried out as part of a programme of the radio research at the Cavendish Laboratory, Cambridge, gives a description of a number of new methods of using the spaced-aerial interferometer and compares their accuracies with those of older methods. Four of the possible methods are dealt with—the periodicity interferometer, the crossed-axis interferometer, the variable-axis interferometer and the double-transit interferometer—and each of these is examined in turn.

It is pointed out that the new methods are particularly applicable to the accurate determinations of the positions of intense radio stars; when the object of the observations is to detect the largest possible number of radio stars, the periodicity interferometer has advantages for declinations greater than about 30°, while the crossed-axis interferometer has advantages at lower declinations. Appreciable refraction may occur at radio wave-lengths in the troposphere and also in the ionosphere; in the former the refraction makes the star appear nearer the zenith than it actually is, and as the refractive index of dry air is practically the same for radio waves as for light waves, the refraction effects correspond closely to the standard astronomical effects.

The refractive index of water vapour is greater at radio wave-lengths than at visual wave-lengths, and hence appreciable deviations at large zenith angles may be caused by a rapid gradient of refractive index caused by a rapid lapse-rate of water vapour. This problem has been dealt with in the Physical and Meteorological Societies' Report (1947); a quotation from a publication shows the magnitude of the correction that is necessary. The total atmospheric refraction at an elevation of 5° was calculated to be 15′, one-third of which was due to water vapour. Irregular ionospheric diffractions occur and are accompanied by changes in the apparent position of the radio star, and this position may vary in a few seconds by 1–2′ of arc on a wave-length of 3·7 m. In addition, regular ionospheric refraction takes place, and the simultaneous reception of radiation from two nearby stars may be responsible for confusion, the resulting error from which is discussed near the end of the paper.

INSTITUTE OF PHYSICS

ANNUAL GENERAL MEETING

At the thirty-third annual general meeting of the Institute of Physics, held on May 29 at Bournemouth, during the second Convention of the Institute, the following were elected to take office on October 1: *President*, Dr. C. Sykes; *Vice-President*, Prof. F. A. Vick; *Hon. Treasurer*, Dr. S. Whitehead; *Hon. Secretary*, Dr. B. P. Dudding; *New Ordinary Members of the Board*, Mr. A. T. Pickles and Dr. P. S. H. Henry. Prof. A. M. Tyndall, a founder Fellow and past-president of the Institute, formerly professor of physics at the University of Bristol, and distinguished for his fundamental work on the mobility of ions and for his services to science and education, was elected to honorary fellowship of the Institute.

The thirty-third annual report of the Board, covering the work of the Institute during 1952, was adopted at the meeting. It records that the Board met six times, and its various standing committees twenty-three times, during the year. The membership increased by 267 to 4,357; but there were small decreases in the numbers of subscribers and student members. The total of those elected to grades of membership for which approved academic qualifications in physics are demanded was the highest since the foundation of the Institute. During the year, the first examination for the recently established graduateship grade took place; twenty-one candidates presented themselves and six satisfied the examiners. The annual report refers to the large increase in interest shown both by employers and colleagues in the National Certificates in Applied Physics. Some slight alterations in the regulations governing these Certificates have recently been made by the joint committee of the Ministry of Education and the Institute responsible for the award and control of the courses. In particular, a practical examination need no longer be held as part of the final assessed examination. For the 1952 examinations there were 137 candidates for the Ordinary and 33 for the Higher Certificate.

About half the work of the Institute is now devoted to its publications, and the magnitude and value of this work can be judged by the fact that receipts from sales, including advertisement revenue, were £28,000 during 1952. The circulation of both the Institute's journals, the *Journal of Scientific Instruments* and the *British Journal of Applied Physics*, continues to increase steadily. The amount of material submitted to the journals in 1952 was similar to that in 1951, but the number of special articles and reports in the *Journal of Scientific Instruments* was rather less than formerly, with more space devoted to original papers. Several new features were introduced into the monthly *Bulletin* circulated to all members; these include invited articles and an annual index. New volumes published during 1952 in the "Physics in Industry" series were "Industrial Magnetic Testing" by Prof. N. F. Astbury and "Metallurgical Equilibrium Diagrams" by Dr. W. Hume-Rothery, Mr. J. W. Christian and Mr. W. B. Pearson. Another interesting publication, "Physics as a Career", written by Mr. N. Clarke, deputy secretary of the Institute, at the suggestion of the Institute's Education Committee, is a guide to the available avenues of training leading to professional recognition as a physicist. A companion volume is the report, "The Scientific Education of Physicists", issued by the Education Committee. This contains details of the physics departments of all the universities and university colleges of Great Britain and of the technical colleges recognized by the Institute. An additional report entitled "Problems concerning the Education of Physicists" will be published shortly.

The Institute continues to be represented on many joint committees and bodies, including government committees and those of the Royal Society, the City and Guilds of London Institute and the British Standards Institution.

The fourth in the series of "Physics in Industry" conferences, and the first since the Second World War, was held in Glasgow during June 25–28, 1952. Its theme was "Physics in the Transport, Shipbuilding and Engineering Industries", and its object, as of those earlier in the series, was "to promote the application of physics to industry by bringing to the attention of industrial executive engineers and scientists recent developments in applied physics and by providing opportunities for the interchange of ideas with and among professional scientists". The conference was presided over by Sir Andrew McCance, and about four hundred people attended. Sir Andrew McCance spoke on physics in the service of metallurgy; Sir Robert Watson-Watt on meteorology in industry; Prof. A. M. Robb on applications of physics in naval architecture; Mr. M. G. Bennett and Mr. T. A. Eames on applications of physics in transport; Mr. A. J. Young on automatic control of industrial processes; and Mr. N. Fleming on noise and its suppression. Dr. D. T. N. Williamson gave a public address, with demonstrations, on physics and sound reproduction, and a discussion was held on the education and training of industrial physicists in Scotland. An exhibition of apparatus, instruments and books was held simultaneously at the Royal Technical College, Glasgow, and a catalogue of the exhibition and a handbook of the conference were published. The generous support of the catalogue by the exhibitors resulted in a handsome surplus of close on £1,000 being added to the Endowment Trust Fund of the Institute.

Details of the various activities of the sixteen local branches and specialist subject groups of the Institute are listed in the report. The Australian Branch held a four-day microscopy conference and exhibition in

Melbourne; the Manchester and District Branch were responsible for a one-day conference on textile physics; and the Scottish Branch arranged a course of eight lectures at the University of Glasgow on the development of concepts of physical science and a course of seven lectures at the University of Edinburgh on semiconductors. The Education Group held a joint meeting with the Acoustics Group of the Physical Society and a conference on school and university examinations in physics. The summer meeting of the Electronics Group took place at the Clarendon Laboratory, Oxford. The X-ray Analysis Group celebrated the fortieth anniversary of the discovery of X-ray diffraction by a two-day conference in London followed by a dinner at which Prof. M. von Laue was the principal guest, and the Industrial Spectroscopy Group was responsible for the Third International Spectroscopy Colloquium held at High Leigh, Hoddesdon, at which many scientists from overseas were present.

Further repairs and improvements were carried out to the Institute's House at 47 Belgrave Square, London; the Institute is again indebted to Mr. R. S. Whipple for another generous donation, this time of £500 to the Furnishing Fund.

CALIFORNIA INSTITUTE OF TECHNOLOGY

ANNUAL REPORT FOR 1951-52

THE annual report of the president of the California Institute of Technology for the year ended June 30, 1952 (pp. v+110; from the Institute, Pasadena, California, 1953), reflects the current concern in the United States over the shortage of scientific and engineering man-power, though the policy of limiting the freshmen to 180 each year has kept the Institute freer of fluctuations than most other institutions, and there is evidence of a slight increase in enrolments generally which should improve the supply in a few years time. Concern is also expressed lest higher education should depend upon any one source of financial support, particularly upon Federal funds; but the financial report which, together with those of the secretary, the deans and administrative officers, and of the several Divisions, is appended to the president's report, shows that of income and expenditure on organized research totalling nearly 11·5 million dollars, 9·6 millions came from the Federal Government for the Jet Propulsion Laboratory, the South Californian Co-operative Wind Tunnel, and the Vista Project, while a further 1·3 millions was received and spent on other research contracts. Gifts for current operations, however, exceeded 1·2 million dollars, and the president points out that, except for the few projects in such fields as nuclear physics and aeronautics, the educational and research work of the Institute is still mainly supported by private funds.

Among the features of the research during the year is the new technique developed in the Division of Biology by Prof. R. Dulbecco for studying those viruses which attack animal tissue, as compared with those which attack only plants or bacteria. The new synchrotron which has been under construction during the past two years has produced electrons with an energy of 525 MeV., and this beam causes the creation of π-mesons. Active study during the past year of the new unstable sub-atomic particles which occur in the cosmic rays has led to the identification of at least five different types of such particles. In the Division of Chemistry and Chemical Engineering the structure of complex molecules is being determined by the electron-diffraction method and by infra-red spectroscopy. Evidence was obtained during the year that a polypeptide helix without 3·6 amino-acid residues per turn is present not only in some synthetic polypeptides but also in proteins like hair, finger-nail, skin, hæmoglobin and serum albumin. The sequence of amino-acids in proteins continued to be studied by chromatographic analysis, and the emphasis in work in chemical engineering is being gradually changed from the study of the equilibrium thermodynamic properties of fluids at high pressures to that of non-equilibrium phenomena, such as thermal and material transfer, under quiescent and convective conditions.

In the Division of Civil, Electrical and Mechanical Engineering and Aeronautics, application of the Institute's electric analogue computor has led, by means of new electric circuit analogies, to the development of a rapid and general method for the static stress analysis of complex structures. A new research programme on the basic insulation characteristics of rotating machine insulation was started, and a new technique developed for use in the high-speed water tunnel permits the determination of the dynamic force coefficients of submerged bodies. Advances were made in two long-range programmes concerned with turbulence and compressible fluid flow, and in the Division of the Geological Sciences, where earthquake records have been studied for more than twenty years, the recent Tehachapi earthquake and its many after-shocks were fully recorded on a dozen instruments in the Pasadena Laboratory and in several field stations. The shock also focused fresh attention on building design for seismically active regions, and the Division of Engineering is engaged in designing structures having maximum resistance and in predicting the behaviour of a given structure.

ENZYMATIC AND CHEMICAL OXIDATION OF DIMETHYLPHOSPHORAMIDES TO BIOLOGICALLY ACTIVE DIMETHYLPHOSPHORAMIDE OXIDES

By J. E. CASIDA, T. C. ALLEN and
M. A. STAHMANN

Departments of Biochemistry and Entomology, University of Wisconsin, Madison

SEVERAL dimethylphosphoramides have been investigated as insecticides, and the group as a whole shows great promise in protecting plants against insect pests by chemotherapeutic action. One of these chemicals, octamethylpyrophosphoramide or 'Schradan', has been developed commercially as a systemic insecticide. These alkylamino phosphates differ from the related toxic alkyl phosphates in that they are generally poor *in vitro* inhibitors of cholinesterase, but nevertheless animals exposed to 2–50 mgm./kgm. show typical symptoms of acetylcholine accumulation[1–4]. Furthermore, these alkylamino phosphates produce a differential *in vivo* inhibition of the peripheral cholinesterase[1,5]. They are relatively ineffective inhibitors of chymotrypsin[6].

ENHANCEMENT IN INHIBITORY ACTIVITY OF DIMETHYLPHOSPHORAMIDES BY LIVER SLICES AND PERMANGANATE

Chemicals (a)	Rel. hydrolysis rate (b)	Relative effectiveness as chymotrypsin inhibitor (c)	Change in effectiveness (d) after reaction with:	
			liver slices (e)	neutral MnO_4^- (f)
(1) 	5·0	4·7	– – –	– –
(2) 	2·9	3·5	– –	–
(3) 	2·8	2·8	–	+

(7) 	—	0·5	++	+++
(8) 	—	<0·1	++	+++

$R = —N(CH_3)_2$ $EtO = —OC_2H_5$

(a) Sources of chemicals: Victor Chemical Co., 1, 7; Bayer–I. G. Farbenindustrie, 2, 5; Monsanto Chemical Co., 3, 4, 6; and Dr. F. I. Edwards, Bur. Ent. and Plant Quar. U.S. Dep. Agric., 8.

(b) Measured manometrically at 37° C. and pH 7·4; half-life of first chemical 2·7 hr.; other chemicals expressed as the logarithm of the relative hydrolysis rate based on 5·0 for No. 1.

(c) Based on negative logarithm of molar concentration required to effect 50 per cent inhibition of esterase activity of 20 γ crystalline chymotrypsin per ml. in M/50 phosphate buffer at pH 6·25 with 16 hr. combination time at 4° C. prior to assay.

(d) Change in inhibitor potency indicated as follows:

– – – = < 1 per cent of original activity
– – = 1–10 „ „ „
– = 10–80 „ „ „
+ = 2–10 fold increase in activity
++ = 10–100 „ „ „
+++ = 100–1,000 „ „ „
++++ = 1,000–1,000,000 fold increase in activity

(e) 5 ml. M/20 phosphoramide incubated with 2·0 gm. fresh rat liver slices in Krebs–Ringer phosphate buffer at pH 6·5 for 3 hr. at 37° C. in 100 per cent oxygen atmosphere, then extracted with 10 ml. of chloroform and successive dilutions of the chloroform extract assayed for inhibitor present.

(f) 10 ml. M/20 phosphoramide incubated with M/20 MnO_4^- in M/10 phosphate buffer at pH 6·5 until MnO_4^- reduced, and then extracted with 10 ml. of chloroform and successive dilutions of the chloroform extract assayed for inhibitor present. (Compound 1 did not reduce the MnO_4^-.)

The dimethyl amide group stabilizes the anhydride bond and makes it very resistant to alkaline hydrolysis[7].

'Schradan' is converted *in vitro* by liver slices[1,3,8], or *in vivo* in mammals or plants[1,9,10] to unstable anti-cholinesterase agent(s)[1], which are effective inhibitors of chymotrypsin[11]. Permanganate oxidation also changed this alkali-stable pyrophosphate to an unstable material capable of inhibiting the enzymatic activity of chymotrypsin[11] and cholinesterase[4]. The active product from this permanganate oxidation was shown to be a compound that phosphorylates the enzymatically active site of chymotrypsin to add one phosphate residue per molecule of chymotrypsin[11]. This chemical oxidation likewise activated *bis*-(dimethylamino)-*p*-nitrophenyl phosphate and *bis*-(dimethylamino)-fluorophosphine oxide[11]. Liver slices were effective in activating the latter compound[4]. The nature of these active substance(s) has not been previously demonstrated.

Our present work is concerned with the chemical nature of the active substances formed biologically from phosphoramides and their relation to the chemical oxidation products. The specificity of this activation is shown in the accompanying table. Permanganate oxidation or incubation with rat liver slices enhanced the acylating reactivity of many dimethylphosphoramides as measured by chymotrypsin inhibition. The initial activity of these compounds as chymotrypsin inhibitors paralleled their relative rates of hydrolysis. A similar correlation has been made with the stability of the anhydride link in dialkyl phosphates and their cholinesterase inhibiting power *in vitro*[12] and in their effectiveness as contact insecticides. The dimethylphosphoramides shown in the table were exposed to neutral permanganate or liver slices in aqueous buffered solutions and the products then extracted into chloroform. Serial dilutions of this chloroform extract were afterwards assayed for chymotrypsin inhibitory activity. As is shown in the last two columns of the table, this activity generally increased by about the same degree with liver slices or permanganate. With octamethylpyrophosphoramide, compound 6, this increase was about one-million fold. Those phosphoramides which showed no increase in activity were the less-stable compounds where the products might have been destroyed prior to partitioning or were poorly extracted into the chloroform. The products of the various reactions were also tested for *in vitro* inhibition of the true cholinesterase of rat brain. The results showed an increased cholinesterase inhibitory activity which generally paralleled the inhibition observed with chymotrypsin.

The nature of the activation of these phosphoramides was further investigated with octamethylpyrophosphoramide or 'Schradan'. The active constituent from its metabolism by rat liver was purified by counter-current distribution utilizing enzymatic assays for determining inhibitor concentration. The active enzyme inhibitor was separated from the bulk of the unmetabolized phosphoramide with three different pairs of solvent systems. The anti-cholinesterase agent produced in plants or by chemical oxidation possessed the same distribution characteristics and activity against cholinesterase and chymotrypsin as that from the rat liver system, indicating the same active product in all cases.

The mode of formation of the active agent, its decomposition to formaldehyde, distribution behaviour, phosphorylating reactivity and biological specificity indicate that the activation process is an oxidation and strongly suggest an oxidation of a nitrogen atom of the phosphoramide. Further evidence for this was obtained from the infra-red absorption of 'Schradan' following oxidation. Several new absorption bands appeared at almost the identical positions as new bands which are formed when tertiary alkyl amines are oxidized to the amine oxide. Like the amine oxides, the new 'Schradan' oxide obtained biologically or with peracetic acid or permanganate was decomposed on heating in acid to an aldehyde and monomethyl amine. The yield of formaldehyde from permanganate or biologically oxidized 'Schradan' was directly proportional to the cholinesterase inhibition. This oxide of 'Schradan' showed weak basic properties, for it was less readily extracted from acid solutions than from neutral or alkaline solutions by chloroform. The oxidation increased the reactivity of the pyrophosphate anhydride bond to form a reactive phosphorylating agent which was readily hydrolysed by either acid or alkali. This increased chemical reactivity would appear to be due to the new positive centre formed by the oxidation of the phosphoramide nitrogen.

A variety of biological tissues were effective in oxidizing 'Schradan'. In addition to the higher plants, yeast and bacteria also produced the active oxidation product. Many different insects treated with 'Schradan' similarly oxidized the absorbed material. The tissues found most active in this conversion were the gastric caeca of the cockroach. The toxicity of 'Schradan' to insects and mammals appeared in all cases to be due to the enzymatic oxidation *in vivo* to yield this highly effective anti-cholinesterase. The widespread distribution of enzyme systems capable of oxidizing 'Schradan' suggests that such systems must have a rather important biological role and that naturally occurring phosphoramides might also be enzymatically oxidized.

Thus, many dimethylphosphoramides are susceptible to enzymatic and chemical oxidation and thus form a new functional group for which we propose the new name 'phosphoramide oxide'. The phosphoramide oxides of phosphoric acid anhydrides are reactive acylating agents and are particularly effective inhibitors of the physiologically important cholinesterase enzymes.

A more complete account of these studies will appear elsewhere.

Publication of this communication is approved by the director of the Wisconsin Agricultural Experiment Station. The investigation was supported in part by the Research Committee of the Graduate School from funds supplied by the Wisconsin Alumni Research Foundation.

INTRA-HELIX S—S LINKED STRUCTURES FOR INSULIN

By Dr. U. W. ARNDT and Dr. D. P. RILEY

Royal Institution, Albemarle Street, London, W.1

We have briefly mentioned elsewhere[1] that we have considered some feasible structures for the insulin molecule by combining the amino-acid sequences of Sanger and his co-workers[2] with the α-helix hypothesis of Pauling, Corey and Branson[3] and arrived at a limited number of solutions. As this work was facilitated by the use of the Hartley–Robinson 'Courtauld' atomic models[4] and as we knew that Dr. Conmar Robinson was himself working on the insulin problem, we delayed publishing a fuller account. Dr. Robinson has now published[5] his results, which differ very considerably from our conclusions.

We wish to say, first, that to regard the α-helix as a perfect and immutable structure is to take a much too rigid view, and one that is not required by its chemistry. While, in a synthetic polypeptide composed of a single type of monomer, nearly complete regularity is to be expected, this is no longer so in a natural protein constituted of many different amino-acid residues. Variations in both the angle and translation of the helix are permissible and may be necessitated by the different *R*-groups. Such variations were allowed at the outset by Pauling and Corey, and the characteristic constants of the α-helix are known to vary in the case of the synthetic polypeptides. Our suggestion is that, in the natural proteins, the variations can occur within one and the same chain. In the work to be described here, therefore, we have not hesitated to include apparently distorted structures because of this possibility of distributing the strain over several residues.

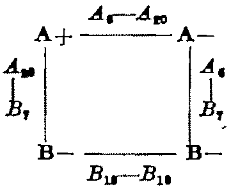
The basis of our present argument is that an intra-helix S—S link exists, and that the insulin molecule consists of two types of polypeptide chains, $\alpha_1(LH,C_\beta 2)$ and $\alpha_2(RH,C_\beta 1)$, both, of course, containing only L–C_α atoms, as previously described[1,6]. These are identified with Sanger's *A* and *B* fractions: $A \equiv \alpha_1, B \equiv \alpha_2$. There is some experimental evidence for this view. The X-ray scattering curve for powdered native insulin appears to fit better a mixture of the two possible variants of the α-helix than either separately, while that for the separated *B*-fraction corresponds more closely to the calculated α_2 intensity function alone. We have not yet obtained any data for the *A*-fraction; but the purpose of this communication is not so much to discuss our experimental X-ray results as to propose possible hypothetical structures for insulin deduced from consideration of the spatial properties of the α_1- and α_2-helices. Nevertheless, it may be that the scattering method will have provided the essential clue to the structure of this molecule.

We differ from Dr. Robinson in allowing the formation of an intra-helix S—S link between the seventh and eleventh residues of the *A*-chain. It thereby becomes possible to consider molecules containing fewer inter-helix S—S bridges, and this permits the employment of both types of α-helix. Previously[1,6], we stated that the presence of proline imposed the α_2-configuration on any chain in which it occurred. This is only partly true, and we should like here to make a fuller statement.

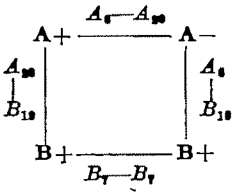
If proline is any one of the first three residues of a polypeptide chain, commencing at the amino end, then the only type of α-helix possible that permits the making of all hydrogen bonds is α_2. Similarly, if proline occurs in the middle of an α-helix, the favoured configuration in the direction of the carboxyl end of the chain will necessarily be α_2. In such a case, on the amino side, the α_2-helix can continue undisturbed for a further three residues only. After this, a disordered (that is, non α-helix) region will arise owing to steric hindrance and the absence of at least one hydrogen bond, and the type of helix, when resumed, is no longer uniquely defined. This disordered region can act as a hinge and permit a change in the direction of the helix axis. In the *B*-chain of insulin, the proline residue is near the carboxyl end of the chain and, therefore, does not necessarily define the configuration in the major part of the helix. Nevertheless, in constructing our models, we have assumed that the whole helix is of the same type, that is, α_2, as suggested by our X-ray data.

It is our belief that the 7–11 S—S link can be made between the C_β atoms in an α_1-type helix if a certain amount of strain and distortion is permissible. A similar link can also be made in an α_2-helix. Approximate figures for the relevant angles and distances are: helix angle, 92°; helix translation per residue, 1·4 A.; H-bond, 2·6 A.; van der Waals radius of —S—, 1·6 A.[4]; C_α—C_β, 1·57 A.; C_β—S, 1·9 A.; S—S, 2·25 A.; $\angle$ C_α—C_β—S, 115°; $\angle$ C_β—S—S, 118°. The C_β—S—S—C_β configuration is roughly intermediate between *cis* and *trans*. These values correspond to one possible compromise solution and can be varied, within limits, if the criteria of choice are altered. If the link is made, it is certainly strained and the regularity of the helix over residues 7–11 is disturbed. Therein, according to a speculative view, might in part lie the high biological activity of the molecule.

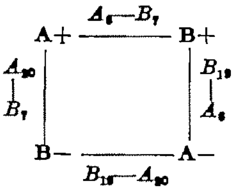
In order to constitute a molecule of weight 11,550, $2A(\alpha_1)$ and $2B(\alpha_2)$ chains must be cross-linked by four —S—S— bonds involving residues 6 and 20 in the α_1- and residues 7 and 19 in the α_2-helices. From our examination of the problem, a cyclic, or closed, arrangement is necessary, in which case there are only the three possibilities shown in the accompanying sketch:



(1)

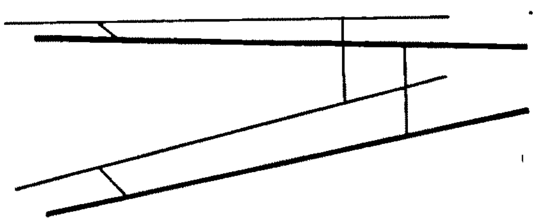


(2)



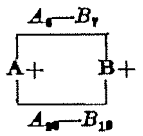
(3)

The + and − signs represent the different ends of the polypeptide chains (—NH_2 and —COOH), and all three arrangements are essentially anti-parallel in nature. The third possibility is accompanied by more strain than are the first two. Only one S—S bridge is formed between any pair of neighbouring helices. It is a necessary feature of these hypothetical structures that the four helices lie inclined to one another, the angle between the axes of adjacent helices being approximately 5°. A rough perspective sketch of the disposition in space is given in the accompanying diagram. There appears to be no steric hindrance whatever between the *R*-groups of adjacent helices, and the nature of the assembly when placed in Sanger's sequences is determined only by the requirements of the four —S—S— bridges across the narrower parts of the molecule. While the molecule has no true symmetry, in a schematic sense its shape is that of a truncated tetragonal sphenoid (4) the length of which is reasonably accurately defined by that of the longer *B*-chain, 45 A.; its 'diameter' is very roughly 25 A. The average distance between the axes of neighbouring helices is about 11 A.

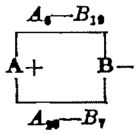


Schematic arrangement of helix axes and —S—S— bridges in closed four-chain structures for insulin

It is interesting to note, in view of the uncertainty regarding the true molecular weight of insulin, that a 'half' molecule of type *A*—*B* and weight 5,775 can be formed if the intra-helix 7–11 S—S link in the *A*-chain exists. The two helices, with $A \equiv \alpha_1$, $B \equiv \alpha_2$, as before, can be doubly cross-linked in the following ways:



(4)



(5)

The axes of the helices are nearly parallel in both cases, although some skewness is possible, and their distance apart is about 11 A.

Miss Cowan and Mrs. Crowfoot Hodgkin[7] have independently arrived at a conclusion similar to ours regarding the feasibility of the 7–11 S—S link, and provisionally favour, from the single-crystal data on insulin, a closed 4-chain molecule. The final decision can only come from a detailed analysis of the crystallographic data, but at least there are now several molecular models to be tested which are capable of adequately precise definition.

We should like to acknowledge the aid given to this and related work by the British Empire Cancer Campaign.

Motility of Insect Tracheoles

THE tracheoles supplying the epidermis in *Rhodnius* are simple or branched tubes, 200–350 μ in length, tapering gradually from a diameter of 0·7–0·8 μ to end blindly at about 0·2 μ. Each is laid down within a single cell, the nucleus of which lies at about one-third of the way along the tube. Once laid down, the tracheoles persist unchanged throughout the life of the insect: they do not shed their cuticular linings at moulting, nor are they converted into tracheæ (cf. Keister[1] on the late stages of *Sciara*).

The tracheoles are by no means inert structures. If a region of the epidermis is deprived of its tracheal supply, and particularly if an organ with a high rate of oxygen consumption is implanted, the tracheoles from the adjacent regions migrate towards the oxygen-deficient zone. Movements up to 1 mm. have been observed. The tips of the tracheoles appear to be attracted to sites of low oxygen tension: little effect is produced by a simple incision in the integument if this is exposed to air; but the tips move actively towards a cut exposed to zero oxygen tension (using pyrogallol). The tracheæ may be widely displaced by the traction exerted upon them by the actively moving tracheoles.

It is this migration of tracheoles which provides for the immediate tracheal supply of implanted organs. Afterwards, the low oxygen tension induces an exceedingly active outgrowth of new tracheæ and tracheoles which are filled with air and become functional when moulting takes place.

If the insect is reared in reduced concentrations of oxygen, there is an increase in the numbers of large tracheæ developed. This is particularly evident in the wing lobes. The general pattern of wing venation is not affected by this altered tracheal arrangement, although minor changes may occur. These observations will be published in full elsewhere.

Observations on *Lebistes reticulatus*

A COMMERCIAL population of *Lebistes reticulatus* was observed for two years and the three following observations were made.

(1) *Exciting action of an extract of domestic flies.* It is known that in its natural habitat *Lebistes* destroys a great many small insects, especially mosquitoes and mosquito larvæ. During the two years we kept this species in an aquarium the fishes were fed on meat and a commercial fish food only.

One day a freshly killed domestic fly was introduced into the aquarium and floated on the surface; the fishes became very excited after a short but clear refractory period. They swam to and fro below the fly and tried to pull it below water and consume it. The following day another fly which had been covered with shellac was introduced into the aquarium, but the reaction was very weak. Visual stimuli therefore appear to play a very small part in this excitation reaction. A few days later some droplets of a colourless extract of about a hundred flies were added to the aquarium water and an intensive reaction followed. It is therefore probable that a water-soluble substance diffused from the fly into the water and is responsible for the reaction observed. Extracts of locusts and caterpillars of *Sphinx convolvuli* and *Mylabris* gave a weak reaction and that of *Dorylus* and *Coprinus* was negative. It therefore seems probable that the exciting factor is fairly specific for the insect concerned. This excitation-provoking substance apparently represents a new group of substances which may be added to the alarm-, smell- and taste-substances examined and described by von Frisch[1].

(2) *Sex-reversion after infectious decimation.* A *Saprolegnia* infection suddenly appeared in the aquarium when it was over-populated, and within three days 70 per cent of the fish had died. The remaining fishes consisted of eighty-six sexually mature females and seven sexually mature males. Within twenty days after the epidemic there were forty-one females which were changing into males, the gonopodia and male colour patterns being almost fully developed. It was noticeable that only the medium-sized sexually mature females showed this change. The small and large sexually mature females were unaffected (see table).

Size (mm.)	No. of males	No. of females	No of intersexes
19	—	2	—
20	1	1	—
21	—	4	—
22	3	2	—
23	3	2	4
24	—	10	10
25	—	3	7
26	—	2	11
27	—	2	3
28	—	2	2
29	—	3	3
30	—	4	1
31	—	2	—
32	—	1	—
33	—	2	—
34	—	3	—
Totals	7	45	41

The sudden change in sex, twenty days after the epidemic, suggests the probability that the toxins excreted by this pathogenic fungus were responsible for the sex reversion. The question that now arises is: Is the sex reversion a specific reaction to *Saprolegnia* toxins, or may it also occur after poisoning by other toxic agents when they remain active for the same period and with the same intensity?

Other aquaria containing fish of the same population also showed sex reversion, but in a much slighter degree.

(3) *Black mutant with abnormal hydrostatic system.* The same population repeatedly produced a few fish which were characterized by black pigmentation and a reduced swimming capacity. They do not swim horizontally, but with the body at an angle of about 30° with the horizontal, the head being in the highest position. The tail moves very quickly and this gives the impression that they have difficulty in swimming upward because of a hydrostatic defect. In fact, these fishes usually remain just above the bottom

of the aquarium or resting upon it, and never take up a more vertical position to feed from the bottom.

Hitherto, none of these fish has reached sexual maturity. These fish are probably mutants in which the black pigment is intensified, together with an air bladder defect. Often these two factors are accompanied by a slight break in the vertebral column due to which the head bends slightly upwards. In all cases so far observed, the intensification of black pigment and the air bladder defect always occurred together. With care, it seems probable that some of these mutants may attain maturity.

These observations form part of investigations which are supported by a grant of the Council for Scientific and Industrial Research, Pretoria.

Fortuitous Xeno-diagnosis of Bat Trypanosomiasis

DURING an investigation on bat malaria on the East African coast, mosquitoes were fed on infected bats to ascertain the possible course of sporogony of the parasite. The contents of the mid-gut of mosquitoes, fed at various intervals before dissection, were then examined, and instead of ookinetes of malaria, numerous flagellates were found in all the specimens. These included the following:

Nycteris capensis (27)

Contents of mosquito gut 15 hr. after feed.	Crithidia scanty
" " " " 19 " " "	Crithidia numerous
" " " " 21 " " "	Flagellates numerous
" " " " 40 " " "	Crithidia numerous

Nycteris capensis (28)

Contents of mosquito gut 11 hr. after feed.	Crithidia numerous
" " " " 18 " " "	Crithidia numerous
" " " " 19 " " "	Crithidia numerous

Trypanosomes in bat blood have been frequently encountered, and in our own investigation the blood of 25 per cent contained these parasites. In bats 27 and 28, however, repeated search of films of peripheral blood failed to reveal trypanosomes; the bone-marrow was likewise negative, but a heart smear of bat 28 exhibited a few trypanosomes.

The trypanosomes were of moderate size and showed small variations in shape and detail (Fig. 1). In Giemsa-stained films, the nucleus was oval and pale (in films subjected to prolonged staining, the nucleus showed an outer paler area surrounding an inner clump of about twelve deeply staining granules), the parabasal body was in the form of a deeply staining bar lying near the nucleus, the cytoplasm was faintly granular and contained 'myonemes', the shape was roughly ventricular with pointed posterior and anterior ends, the undulating membrane was poorly developed and the flagellum was usually prolonged for a short distance beyond the anterior tip. The flagellates (Fig. 2) in the insect were motile and all appeared to be in the crithidial stage. Many dividing forms were seen and there was a great diversity in shape and size.

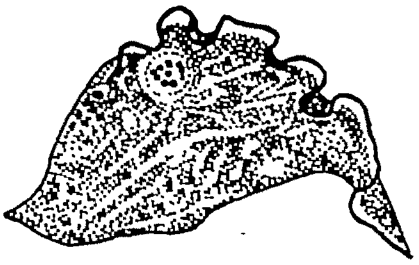

Fig. 1. (× 1,750)

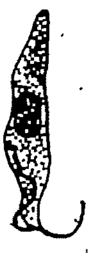

Fig. 2

Little is known about transmission of bat trypanosomes; mites have been incriminated on a few occasions, but in this study no developmental forms were found in sections of mites or in streblids, nor in a tick fed 24 hr. before dissection. On the other hand, development and multiplication took place very rapidly within the mid-gut of mosquitoes (*Aedes simpsoni* and *A. lineatopennis*), and this fact suggests that a mosquito may be the vector in Nature, probably entailing development in the posterior station.

The chief object of this communication is to direct attention to xeno-diagnosis as a means of detection of occult trypanosome infections in bats, a method which is in common use in Chagas's disease for revealing *T. cruzi*. The identity of this bat trypanosome is doubtful, though the dimensions (34–38 μ total length, 14 μ breadth, flagellum not more than 8 μ free) and general characters bring it close to *T. heybergi* Rodhain 1923[1].

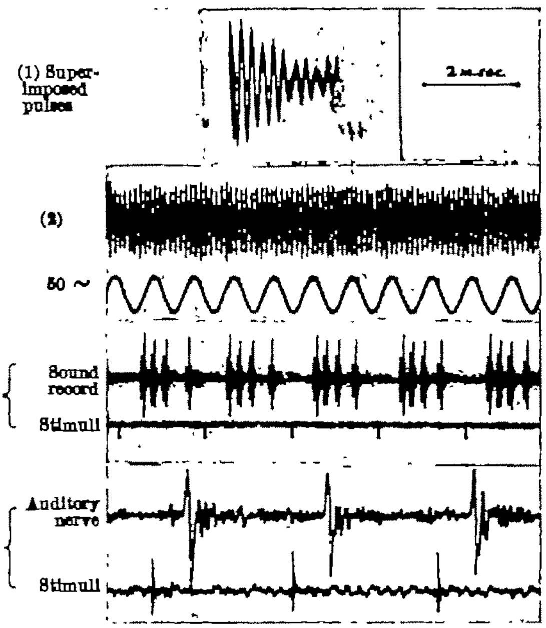
Physiology of Song in Cicadas

SINCE Myers[1] published his monograph in 1929 on this group of insects, only Pierce[2] has re-investigated the song by modern instrumental methods, and there has been no examination of the physiology of the structures involved in sound production. This communication gives a preliminary report of results obtained with the large *Platypleura capitata*, (Oliv.), in Ceylon.

The normal song of this species is shown in records 1 and 2. The sound consists of a train of damped oscillations at a fundamental frequency of about 4,500 per sec., the pulse repetition frequency being about 390 per sec. Both frequencies vary slightly in individuals and are related to the size of the insect, the internal air cavities being resonant at the fundamental.

The sound is produced by the 'ring' of the tymbals when they are suddenly distorted or return to their normal shape; one of these movements is normally more effective than the other in producing sound, depending on the extent of damping by the tymbal muscle and the resonance of the air cavities. The tymbal muscles contract at each pulse, and act synchronously in full song.

Sound production may be induced in the laboratory by electrical stimulation of the nerve to one tymbal muscle. At low frequencies of stimulation, the muscle responds with a series of contractions to each nerve impulse (record 3), and at stimulus frequencies above about 60 per sec. goes into continuous activity at a frequency which is unrelated to the frequency of stimulation. In this behaviour it resembles the indirect flight muscles of Diptera and Hymenoptera studied by Pringle[3] and Roeder[4]. Since the whole



(2), (3) and (4) are on the same time-scale

structure with its nerve is easily dissected free from the rest of the body, there is here a convenient preparation for the study of this type of muscle.

In the field, the local population of male cicadas normally sing in chorus; but Fabre[5], firing a cannon near a group of insects, was unable to detect any response to the noise. Impulses may readily be detected in the auditory nerve from the tympanal organ of the male or female, which is very sensitive to high-pitched sounds. The response in the auditory nerve of a male to the sound of another cicada played back from a magnetic tape recorder is shown in record 4, the synchronous volleys of nerve impulses corresponding to the pulse frequency, with some after-discharge. This auditory organ therefore behaves like other insect 'ears' in responding to the modulation envelope[6]. During song, the tympanum of the male is creased by the action of a detensor muscle which always contracts before the tymbal comes into operation. This explains Fabre's failure to get any response from a group of singing insects.

This work is being conducted while on leave from the Department of Zoology, Cambridge, and is assisted by a Leverhulme Research Fellowship. Some of the apparatus used was purchased with the help of the Government Grants Committee of the Royal Society. The full results will be published elsewhere.

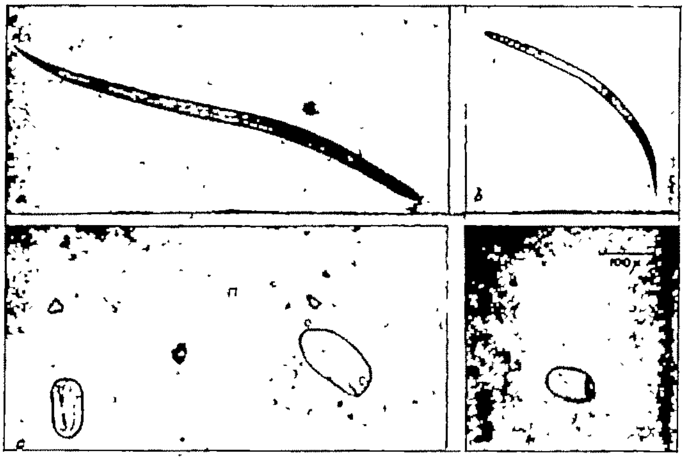
Giant Larvæ of the Potato Root Eelworm, *Heterodera rostochiensis* Wollenweber

It was thought interesting to report the occurrence of a number of giant first-stage larvæ among the progeny of a single female (cyst) of the potato root eelworm. Altogether a total of four giant larvæ emerged on three consecutive days from a single cyst together with a large number of larvæ of normal size. When the cyst contents were examined on the cessation of hatching, no further large larvæ were found, nor any full eggs of unusual size: however, two very large empty egg-cases were noted (Fig. *c*).

	Length (μ)	Breadth (μ)	Stylet length (μ)	Length/breadth
Giant larva 1	817	27	33	25/1
Giant larva 2	783	27	33	24/1
Normal larvæ (mean and S.D.)	463 ± 20·5	18 ± 1·1	24	26/1
Giant egg 1	152	76	—	2/1
Giant egg 2	121	67	—	1·8/1
Normal eggs (mean and S.D.)	103 ± 5	58 ± 5	—	1·8/1

The dimensions of normal and giant larvæ and eggs presented in the accompanying table show that the giants are almost twice the size of normal larvæ. There is little doubt that the large empty cases had been occupied by the giant larvæ, for a rough calculation shows that the volume of the giant larvæ fits that of the large egg-cases fairly well.

So far as I am aware, this is the first record of giant first-stage larvæ in the potato root eelworm, or, indeed, in any root eelworm. According to Goodey, Debray and Maupas found large and normal adults of the related stem eelworm, *Anguillulina dipsaci*, attacking broad beans in and around Algiers (original account not available). The larger forms were 30–50 per cent greater than the normal size for this form; this is considerably less than the increase in the present case. These workers suggest that the large forms were due to environmental causes. Goodey found a wholly giant race of the same species, approximately the same size as the large forms of Debray and Maupas, attacking broad beans in Portugal and Great Britain[1]. He showed, in his case, that the larger size was not due to environmental factors.



(*a*) Giant larva; (*b*) normal larva; (*c*) large egg case and normal egg; (*d*) normal egg case. All photographs are to the same scale

In the present case, since the giant and normal forms are among the progeny of a single female, environmental factors can be ruled out. The main possibilities, therefore, are gene mutation and polyploidy. It is hoped that a study of the cell and nuclear size of normal and giant forms will yield further evidence for or against polyploidy.

Artificial Infection of Various Molluscs with *Mytilicola intestinalis*, Steuer

Mytilicola intestinalis is common in the mussel, *Mytilus edulis*, at several points around the coast of Britain. It has also been reported from oysters, *Ostrea edulis*[1]. In an effort to determine the conditions governing the infection of oysters, and the extent to which other molluscs may act as a reservoir of *Mytilicola intestinalis*, a number of artificial infections have been attempted.

The potential host molluscs were kept in tanks in 5–15 l. of sea-water in a cool basement (5°–10° C.), with constant aeration, and were fed on a culture of *Chlorella stigmatophora*. With the exception of *Chlamys varia*, no difficulty was experienced in keeping them healthy for at least six weeks.

Copepodid stages of *Mytilicola intestinalis* were obtained by allowing egg-sacs to hatch in about 200 ml. of filtered sea-water at 18° C. Copepodids were added to the tanks containing the molluscs over a period of about a week. About two weeks after the last addition of copepodids, the guts of the molluscs were dissected out, opened along their length and examined for parasites under a binocular microscope. All parasites recovered were 0·25–0·5 mm. in length.

Mytilus edulis, *Ostrea edulis*, *Cardium edule*, *Crepidula fornicata* and *Paphia pullastra* were successfully infected in this manner (see table). Attempts to infect *Scrobicularia plana*, *Chlamys varia*, *Pecten maximus* and *Macoma balthica* were unsuccessful. It is of interest that *Mytilicola orientalis*, Mori, has been reported from a wide range of molluscs[2], including *Paphia staminea* and *Crepidula*.

Host	Sample size	Hosts infected	Total parasites	Maximum parasites per host
Mytilus	20	16	52	7
Cardium	10	4	10	5
Ostrea	16	7	17	6
Paphia	10	7	11	3
Crepidula	13	4	7	3

An intensive examination of oysters from areas adjacent to mussel beds infected with *Mytilicola* has failed to reveal any further natural infection of oysters[1]; but one *Cardium edule* in a batch of twenty examined from Poole, Dorset, contained one female *Mytilicola*, 3·7 mm. in length. An examination of all likely hosts is being made, and further infection experiments are in progress.

Phagotrophy in *Oxyrrhis marina* Dujardin

Phagotrophy in the Protista has the particular interest that it offers the possibility of shedding light on the origin of the habit. However, the pure culture of phagotrophs, so necessary for their study, presents considerable difficulties; to my knowledge, only one obligate phagotroph has yet been successfully grown thus, *Peranema trichophorum* Ehr.[1]. *Oxyrrhis marina* Dujardin, the common dinoflagellate of the brackish supra-littoral, is extremely easy to culture and offers a challenge to all interested in phagotrophy.

O. marina is normally kept in bacteriologically pure culture but fed at intervals from a culture of the yeast *Saccharomyces exiguus*. It will thrive as well on pure cultures of phytoflagellates such as *Brachiomonas submarina*; single cells of *O. marina* transferred to thriving cultures of the phytoflagellate or to culture media with a little of the living yeast multiply well. No multiplication takes place, however, if the yeast cells are killed by heating up to 70°, and neither filtrates from yeast cultures nor unautoclaved, filtered autolysates of the yeast support growth. Commercially prepared yeast and beef extracts and peptones were ineffective, whether they were autoclaved or filtered. 0·25 per cent milk, pasteurized, will not support growth unless some of the yeast, however little, is introduced also, when cultures of extreme density ensue. On the face of it, therefore, it appears that *O. marina* is an obligate phagotroph and, further, some living cells must be among its food.

In the course of many experiments involving the isolation and washing of single cells and transferring them to media of various descriptions, pure cultures were obtained on two occasions in a liquid medium with particulate nutrients. The successful medium was an autoclaved mixture of yeast and beef extracts with certain B vitamins in addition. In the most successful of the cultures, counts showed that the single cell had multiplied to 250,000, which represents about eighteen generations. All attempts to make subcultures from them met with complete failure, even though an identical medium was employed. It seems, therefore, that the reason for the success of the two cultures did not lie with the known constituents of the medium.

The possibility of chance introductions has to be kept in mind; but the following substances were ineffective: burned or unburned cottonwool, detergents including 'Tween' 80, burned peptone, irradiated peptone, alkali-treated peptone, Evans's peptone, liver infusion, ergosterol, thiamin, riboflavin, niacin, pantothen, pyridoxine, folic acid, *p*-amino benzoic acid, biotin and ascorbic acid. The other possibility is that the single cell with which the cultures started chanced to contain within itself enough reserve of the required substance to supply 250,000 cells.

These experiments demonstrate that *O. marina* need not be dependent on phagotrophy for its gross nutrients. The behaviour is most easily explained by the assumptions that: (1) there are one or more growth-factors to which the cell membrane is impermeable; (2) these factors are present in living but absent from heat-killed cells; and (3) they are required in very small quantity.

An interesting comparison is afforded by *Peranema trichophorum* in which there is obligate phagotrophy but no dependence on living cells for food; this organism can be grown successfully in pure culture on

0·1 per cent milk[1]. It would seem that phagotrophy in *O. marina* and *P. trichophorum* is due to different causes.

The Australopithecine Milk Canines

We have previously discussed[1,2] the classification of lower milk canines by multivariate statistical analysis. By this means we have shown that the Taungs and Kromdraai specimens found in South Africa are neither those of chimpanzees, gorillas nor orang-utans and that, in tests based on four carefully chosen dimensions of the specimens, they cannot be distinguished from the teeth of humans.

By the courtesy of Mr. J. T. Robinson, we have now been able to apply these methods to six other lower milk canines found in South Africa. One of our tests[1,2] employed the discriminant function,

$$X = x_1 - 7{\cdot}49x_2 + 2{\cdot}34x_3 + 4{\cdot}70x_4,$$

where x_1 is the height, x_2 the maximum anterior–posterior length of the upper half, x_3 the maximum breadth of the upper half, and x_4 the maximum anterior–posterior length at the level of the basal cingulum of the specimen (all measured in millimetres). The values of X for all eight fossil specimens are given in column 1 of the accompanying table. All are negative; that is, all fall outside the range for apes[2] and within the human range. We can therefore conclude definitely that none of these teeth can be assigned to the apes; and, tentatively, that they are of hominid origin.

	X	*S*
Kromdraai	−2·6	1·0
Taungs	−7·9	5·9
Swartkrans *SK* 61 (left)	−6·9	2·8
Swartkrans *SK* 61 (right)	−9·1	6·7
Swartkrans *SK* 62	−7·5	6·7
Swartkrans *SK* 63	−5·4	4·9
Sterkfontein (left)	−2·1	11·9
Sterkfontein (right)	−4·4	10·6

The second conclusion remains tentative so long as the tests are confined to the discriminant X. For the discriminant is essentially a comparative test: a device to decide which of two or more stated alternatives is to be preferred. The analysis was therefore pressed further, to discover how closely, in an absolute sense, these teeth resemble human milk canines.

This question is answered by a second multivariate function, the generalized distance. This statistic sums up, in one quantity, the divergence of the complete set of measurements of the specimen from their means in the group with which it is being compared (making allowances for the variances of the measurements and the correlations between them). It is thus a mathematical measure of the absolute resemblance of the specimen to the group as a whole.

Using the same four dimensions, x_1, x_2, x_3 and x_4, and the same basic material which yielded the discriminant, we constructed[2] such a generalized distance function for human milk canines. Its most convenient form is the sum of squares

$$S = (y_1-6{\cdot}53)^2 + (y_2-11{\cdot}96)^2 + (y_3-4{\cdot}99)^2 + (y_4-1{\cdot}91)^2,$$

where the y's are obtained from the x's by the relations

$$\begin{aligned} y_1 &= x_1, \\ y_2 &= -0{\cdot}345x_1 + 2{\cdot}605x_2, \\ y_3 &= 0{\cdot}078x_1 - 0{\cdot}586x_2 + 2{\cdot}337x_3, \\ y_4 &= -0{\cdot}124x_1 - 1{\cdot}159x_2 - 0{\cdot}119x_3 + 2{\cdot}050x_4. \end{aligned}$$

The value of S for a specimen is always positive, and the larger S is the smaller is the resemblance to human teeth. On the average, S will exceed 6·0 in only 5 per cent of human specimens; and it will exceed 8·4 in only 1 per cent of human specimens. (These percentages are estimated from the measurements of modern European lower milk canines. It may be expected that they would be somewhat larger if the measurements were extended to include other races.)

The values of S for the South African finds are given in column 2 of the table. They demonstrate the resemblance between these teeth and modern human milk canines. Four values of S lie within the range which encloses 95 per cent of modern human values, and two others lie close to it. The Sterkfontein pair alone is unacceptably remote; a value of S as high as these would be expected to occur in modern European man only once in a thousand times.

For completeness, we should add that the closest resemblance we have found between the individual fossils and the ape groups is between Sterkfontein (left) and the orang-utans, and this corresponds to an S-value of 13·6.

The fossil teeth, it is interesting to note, form a quite compact group. The dimensions x_1, x_2, x_3 and x_4 vary appreciably from one member of the group to another; but we have examined this variation, and it is, in fact, somewhat smaller (though not significantly so) than in our modern human group. The Sterkfontein teeth do not differ significantly from the others within the fossil group, and it seems possible to regard their differences from the human group merely as the outstanding symptom of a general slight departure of the fossils from the human average. The mean dimensions of the fossil group would give an S-value of 4·1, which (since we are now dealing not with an individual result but with the mean of several) is much higher than would be expected if the teeth were all modern human. The difference remains significant if we discard the Sterkfontein finds, and indeed if we confine ourselves to the sub-group of four Swartkrans teeth.

To complete the picture, we examined the resemblances between the mean of the fossil group and each of the ape-groups. We found that the closest resemblance of these was to the orangs, and corresponds to an S-value of 18·9.

To sum up, our analysis shows that the fossil milk canines, on this evidence, form a rather homogeneous group; that as a group they are very similar to those of modern European man; and that they are on the whole unlike those of the modern anthropoid apes.

Zymasis and Acid Metabolism in Higher Plants

CONSIDERABLE attention has been directed to zymasis (alcoholic fermentation) as a component of anaerobic metabolism in higher plants; but relatively little is known of the accompanying biochemical disturbances. In many tissues zymasis is suppressed by oxygen in concentrations less than 2 per cent[1]. In air it is normally absent; but certain agents, for example, carbon dioxide in high concentration[2], can induce the accumulation of ethyl alcohol with acetaldehyde.

In plants showing crassulacean acid metabolism, carbon dioxide is fixed into malic acid in a dark reaction[3]. Acid synthesis is promoted by feeding carbon dioxide in concentrations up to 5 per cent; above 10 per cent, acidification is progressively retarded until above 50 per cent it is very slow or stopped and alcohol accumulates[4]. Moreover, acidification occurs only when the oxygen concentration is above about 1 per cent[5].

Inasmuch as the distinguishing characteristic of crassulacean acid metabolism appears to be the potential magnitude of the dark fixation rather than the event itself[4], it seemed possible that the broad correlation between disturbed acid metabolism and onset of zymasis might have some general significance. Exploratory experiments were carried out by chromatographic analysis of the water-soluble components of the plant tissues, and by the comparison of the chromatograms obtained from tissues after storage in one or other of a variety of gas mixtures with those obtained from the normal tissue in air. Aliquots of the aqueous extracts were chromatographed in two dimensions in *tert.* amyl alcohol/formic acid/water, and *n*-propanol/ammonia/water mixtures, or in one direction, after fractionation on ion-exchange resins, in one or other of the solvents.

The broad changes in a limited number of the more prominent components of the chromatograms in a series of experiments with *Kalanchöe* leaves, carrot roots and oat coleoptiles are summarized in the accompanying table. The amino-acid identified as γ-amino-butyric acid co-chromatographed consistently with an authentic specimen (kindly supplied by Dr. S. M. Partridge), and the identity is accepted provisionally.

Plant organ and storage time (20° C.)	Treatment	Citrate	Malate	Succinate	Aspartate	Glutamate	Alanine	γ-Amino-butyrate
Kalanchöe leaves (12 hr)	*a*	+	+	−	+	+	−	−
	b	+	+	−	+	+	−	−
	c	+	−	+	−	−	−	+
	d	+	+	+	−	−	−	+
Young carrot root (3 days)	*a*	−	+	−	+	+	+	−
	b	−	+	−	+	+	+	−
	c	−	−	+	−	−	−	+
	d	−	+	+	−	−	+	+
Older carrot root (3 days)	*a*	+	+	−	+	+	+	−
	b	+	+	−	+	+	+	−
	c	−	−	+	−	−	−	+
	d	+	+	+	−	−	+	+
Oat coleoptile (1 day)	*a*	−	+	−	+	+	+	−
	b	−	+	−	+	+	+	−
	c	−	−	+	−	−	−	+
	d	−	+	+	−	−	+	+

Occurrence of some acids and amino-acids in plant tissues after storage in gas mixtures: (*a*) air; (*b*) 2–10 per cent carbon dioxide in air; (*c*) 20–90 per cent carbon dioxide with oxygen; (*d*) pure nitrogen, carbon dioxide, or 1 per cent oxygen in nitrogen. + indicates high (relative) concentration, − low concentration.

In concentrations of carbon dioxide less than 10 per cent there was no major change in acid composition. Between 20 and 90 per cent carbon dioxide, succinate and γ-amino-butyrate accumulated, whereas malate, aspartate, glutamate and alanine were depleted. Alcohol accumulation as a result of carbon dioxide zymasis has been observed in many higher plants, but not as yet in concentrations much below 50 per cent[2]. It remains to be seen whether or not more sensitive techniques will detect alcohol accumulation in 20 per cent carbon dioxide.

Zymasis in nitrogen, 1 per cent oxygen, or pure carbon dioxide was accompanied by the accumulation of succinate and γ-amino-butyrate, and the depletion of aspartate and glutamate. Malate and alanine remained unchanged in the storage periods arbitrarily selected for these experiments.

The depletions of the amino-acids suggest parallel changes in the corresponding keto-acids, and this is being investigated.

Carrot and *Kalanchöe* tissues, when aerated in $M/30$ malonate in phosphate at pH 4·5, accumulated succinate without appreciable change in citrate or malate. The aspartate, glutamate and alanine contents were not markedly changed; but some γ-amino-butyrate accumulated. Since this amino-acid was present, though to a less extent, in control experiments in phosphate alone, it is possible that the accumulation was not directly attributable to the malonate; but the occurrence of malonate zymasis has been reported recently[6].

Clearly, in the types of zymasis studied, disturbances in acid metabolism occurred, and one result common to all was the accumulation of succinate.

For *Kalanchöe* leaves some indication of the main source of this succinate in carbon dioxide zymasis can be derived from the following experiments. (1) Exposed to carbon dioxide labelled with carbon-14 in the dark at 10° C. for periods of less than 6 hr., these leaves accumulate carbon-14 very largely in malate. (More than 60 per cent of this carbon-14 may be in the β-COOH group.) When leaves containing malate labelled by this treatment were transferred to 70 per cent carbon dioxide, no carbon-14 could be detected in the accumulated succinate or in any alcohol accumulating. The carbon dioxide liberated contained carbon-14. (2) When leaves, in which both sugars and malate were labelled after photosynthesis in carbon-14 dioxide, were transferred to 70 per cent carbon dioxide, carbon-14 was detected in the accumulated succinate and the alcohol fraction as well as in the carbon dioxide evolved. In neither type of experiment was appreciable accumulation of carbon-14 detected in any other acid or amino-acid during the zymasis.

Tentatively it is visualized that, in air, pyruvate is oxidized in a Krebs acid cycle; in carbon dioxide zymasis, (*a*) the accumulated succinate is not in the main derived from malate by a conversion in the acid cycle, (*b*) malate is depleted with decarboxylation to pyruvate, and (*c*) the pooled pyruvate is converted in part to acetaldehyde and ethyl alcohol and in part to succinate.

Glutamotransferase in the Chick Embryo during Incubation

IN recent years the role of glutamine in the metabolism of nitrogenous compounds and in peptide synthesis has attracted increasing attention[1]. Much may be learned about the function of a compound in fundamental biochemical processes by studying the enzymatic system concerned with its metabolism during growth and differentiation. As a first contribution to this problem, we wish to report on the distribution of glutamotransferase in the chick embryo during development. This enzyme catalyses the exchange of the amide group with hydroxylamine or other amines. For full activity, glutamotransferase from mammalian and avian tissue requires manganous salt, phosphate and traces of adenosine triphosphate.

Freshly made homogenates of various embryonic areas or organs in phosphate buffer (0·02 *M*, *p*H 7·3) served as the source of glutamotransferase. Before incubation, no activity could be demonstrated in the fluid yolk, the egg albumen or the vitelline membrane. Likewise we have not been able to demonstrate transferase activity in the unincubated blastoderm, or in the pellucid area during the first and second days of incubation. These negative findings should not be interpreted as necessarily indicating the total absence of the enzyme in these regions.

Unequivocal transferase activity was first demonstrable in the area opaca after incubation for 24 hr. The area opaca and its major derivative, the yolk sac, remain the chief sites of transferase activity until late in the second half of incubation; although, as the embryo differentiates histologically, certain of its tissues acquire a specific activity as high as, or higher than, that of the yolk-sac tissue. The volume of these active tissues (liver, brain and, to a lower degree, heart and stomach) is, however, so slight as to contribute little to the total activity of the embryonic system until considerable growth has taken place.

Protein content and transferase activity were determined on each day of incubation. In the accompanying table the results obtained at the sixth, thirteenth and sixteenth day of incubation in brain, liver and yolk sac are shown; the rest of the tissues of the system embryo minus liver and brain, and other membranes, are grouped as 'remainder', in which only a minimal specific activity is found. The total (100 per cent) was arrived at by summation of the values determined on the individual organs. The following points seem to us the most significant:

(1) Transferase activity increases *pari passu* with protein growth in the total embryonic system. Spatial distribution of the activity, however, is not even, and these inequalities change progressively.

(2) The yolk sac, which begins by containing most of the protein in the system, contributes even more than its share of transferase activity to the whole. This situation is reversed shortly after the thirteenth day of incubation, at which time the yolk sac contributes about 35 per cent of the protein and about half the total activity. After this day, the specific activity of the yolk-sac tissue declines to the general low embryonic level, so that by the sixteenth day this tissue contributes only 17 per cent of the activity, although it contains 26 per cent of the protein.

(3) The liver, when still a minute organ, before its cells start visibly producing bile pigments or storage products, has a specific activity much higher than any other tissue of the system, contributing more than 1 per cent of the total activity when its protein content is considerably less than 1 per cent (six days). Its contribution steadily increases at a rate greater than that of its protein content, thus gradually helping to balance the loss of activity in the yolk sac.

(4) The brain, in contrast, although constituting a major structure of the early embryo, has a low transferase activity, indistinguishable from the general embryonic level, during the first half of incubation. After that time, its activity begins to rise progressively, so that by the end of incubation its contribution to the total activity approximates that of the liver.

This work was supported in part by grants from the National Institute of Neurological Disease and Blindness (Grant *B*-226) of the National Institutes of Health, Public Health Service, and a grant from

Days of incubation	Tissue	% Protein	% Activity	Specific activity
6	Total	100 (=68 mgm.)	100 (=5·0 μM GHA*)	0·07
	Liver	0·3	1·3	0·31
	Brain	3·3	0·5	0·02
	Remainder	13·4	3·7	0·02
	Yolk sac	83 0	94·5	0·08
13	Total	100 (=635 mgm.)	100 (=42 μM GHA)	0·07
	Liver	3	20	0·45
	Brain	4	6	0·10
	Remainder	58	23	0·06
	Yolk sac	35	51	0·10
16	Total	100 (=1,388 mgm.)	100 (=49 μM GHA)	0·04
	Liver	2·4	30	0·44
	Brain	3	14	0·18
	Remainder	68·6	39	0·02
	Yolk sac	26	17	0·02

* GHA = Glutamohydroxamic acid

The complete assay system contained, per 2 ml. of 0·05 *M* acetate (*p*H 5·5): glutamine 40 micromols, hydroxylamine 20 micromols, phosphate and manganous chloride 10 micromols, adenosine triphosphate 0·1 micromol and an amount of homogenate which permitted the determination of initial rate of glutamotransferase activity. Incubation, 1 hr. at 37°; GHA determined by the ferric chloride reaction (ref. 2) and protein content by the quantitative biuret reaction (ref. 3) or the modified Folin method (ref. 4).

The figures are calculated for one embryo and are expressed as percentage of the total (100 per cent); absolute values of protein content and activity are given in brackets.

Activity: micromols of glutamohydroxamic acid produced in one hour at 37°.

Specific activity: micromols of glutamohydroxamic acid produced per milligram of protein per hr. at 37°.

18 embryos used at six days of incubation, one embryo each at 13 and 16 days.

Pathway for Glucose Oxidation in *Asterococcus mycoides*

IN those species of bacteria examined which oxidize glucose but are incapable of attacking it anaerobically, it has been shown that glucose breakdown proceeds by a pathway other than through the classical Embden–Meyerhof scheme[1]. Cell suspensions of *A. mycoides* (the organism of bovine pleuropneumonia) were found to oxidize glucose, but were incapable of attacking it anaerobically. Consistent with this finding is the fact that growth was almost absent under anaerobic conditions, and was markedly stimulated by aeration of cultures. In spite of the absence of anaerobic glucose breakdown, it is concluded that glucose oxidation in this organism proceeds by way of the Embden–Meyerhof pathway.

Glucose was oxidized by cell suspensions (Q_{O_2} 60–80) quantitatively to acetate and carbon dioxide. Methylene blue, ferricyanide or diphosphopyridine nucleotide could all replace oxygen as electron acceptor. Pyruvate was oxidatively decarboxylated, and was also attacked anaerobically by the dismutation reaction. Evidence was obtained that the dismutation system was similar to that described in *Escherichia coli* and *Streptococcus faecalis*[2], that is, a diphosphopyridine nucleotide-linked, pyruvic-lactic dehydrogenase system, requiring coenzyme A, cocarboxylase, magnesium ions and phosphate as acetyl acceptor. Both the oxidation and dismutation of pyruvate were strongly inhibited by arsenite.

Glucose oxidation was inhibited by iodoacetate. Evidence was obtained for the presence of hexokinase. The cells possessed aldolase activity, as determined by alkali-labile phosphate formation in the test system of Sibley and Lehninger[3]. A cell-extract prepared by grinding lyophilized cells with alumina grinding powder had an activity, expressed as μl. hexose diphosphate split per mgm. bacterial protein per hour, of 250. None of the phosphorylated hexose intermediates was oxidized by intact cell-suspensions. Suspensions treated by freezing and thawing, however, oxidized glucose-6-phosphate and hexose diphosphate at approximately the same rate as glucose, but did not attack gluconate or 6-phosphogluconate.

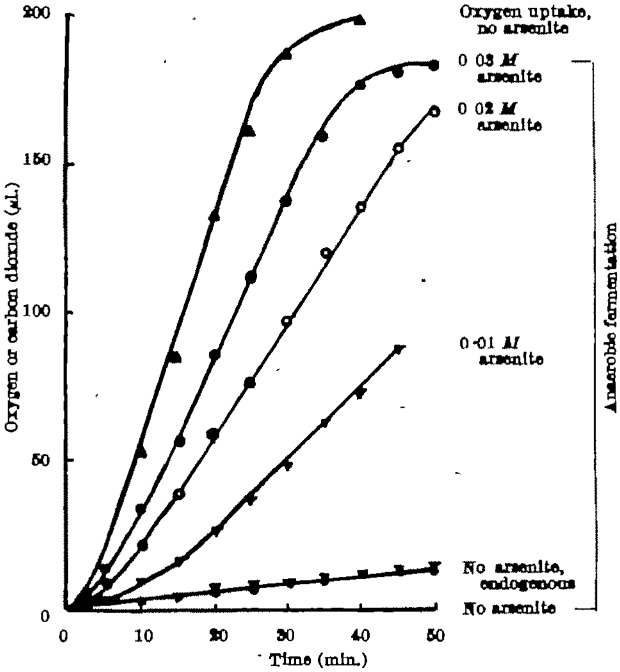
In contrast to intact cell suspensions, suspensions treated by freezing and thawing were capable of a very slow glucose breakdown anaerobically. The rate was very markedly increased when the reaction was linked with the reduction of acetaldehyde by yeast alcohol dehydrogenase (see table). In the presence of arsenite to inhibit the pyruvate dismutation reaction, intact cell-suspensions catalysed a homolactic glucose fermentation at a rate comparable with the rate of glucose oxidation (see graph).

EFFECT OF LINKING ANAEROBIC GLUCOSE BREAKDOWN BY *A. mycoides* WITH REDUCTION OF ACETALDEHYDE BY YEAST ALCOHOL DEHYDROGENASE

Complete system: Frozen and thawed suspension = approx. 1·5 mgm. nitrogen; magnesium chloride, 30 μM; alcohol dehydrogenase solution in M/20 phosphate buffer containing 0·1 per cent bovine albumin, 0·4 ml.; glucose, 5 μM; acetaldehyde, 10 μM; sodium bicarbonate, 60 μM; fluid vol., 3·0 ml.; 7 per cent carbon dioxide in nitrogen (v/v) in gas phase

Components	Rate (μl. carbon dioxide/hr.). Experiment 1	2
Complete system	135	233
Without alcohol dehydrogenase	59	61
,, acetaldehyde	80	120
,, alcohol dehydrogenase, acetaldehyde	70	63
,, glucose	13	28
,, glucose, alcohol dehydrogenase, acetaldehyde	8	26

It was concluded that oxygen (or other electron acceptor) is required for the re-oxidation of reduced diphosphopyridine nucleotide formed by the oxidation of triose phosphate. In the absence of oxygen, pyruvate is bound by the dismutation system, and is not available for reduction to lactate in the glycolysis scheme. The reaction therefore ceases when all the diphosphopyridine nucleotide has been reduced. The organism possesses no other mechanism for the re-



Effect of arsenite on rate of anaerobic glucose breakdown by intact cell suspensions of *A. mycoides*

Anaerobic fermentation: 0·075 M sodium bicarbonate, 0·5 ml.; bacterial suspension, 0·5 ml.; arsenite solution, 0·25 ml.; M/20 glucose, 0·1 ml.; water to 1·5 ml. 5 per cent carbon dioxide in nitrogen in gas phase.

Oxidation: M/5 phosphate buffer, pH 7·4, 1·5 ml.; bacterial suspension, 0·5 ml.; M/20 glucose, 0·1 ml.; 20 per cent potassium hydroxide, 0·2 ml. (centre well) oxidation of reduced diphosphopyridine nucleotide under anaerobic conditions, for example, α-glycerophosphate dehydrogenase. It must be assumed that, in organisms which are capable of a homolactic fermentation, and which also possess the pyruvate dismutation system—for example, *S. fæcalis*—pyruvate combines preferentially with lactic dehydrogenase. A number of explanations are possible for the different behaviour of *S. fæcalis* and *A. mycoides*, such as the relative affinities of pyruvic oxidase and lactic dehydrogenase for pyruvate; the relative concentrations of the enzymes; or differences in macromolecular organization within the cells. The last possibility is plausible, since cells of *A. mycoides* treated by freezing and thawing are capable of a slow glucose fermentation, and the rate of the pyruvate dismutation reaction is considerably decreased by freezing and thawing.

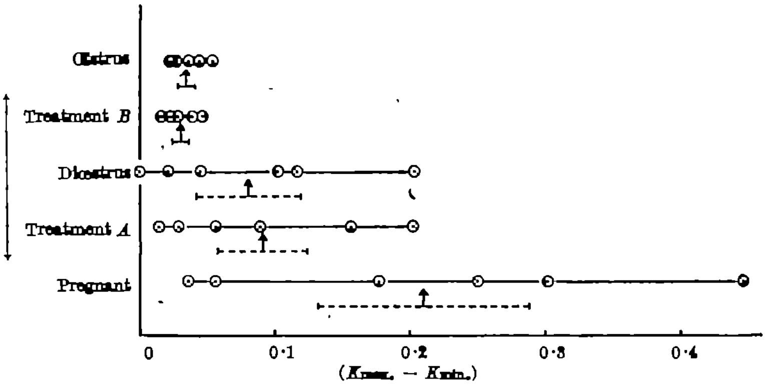
Ultra-Violet Absorption Spectra and Flow Birefringence of Bovine Cervical Secretions

SECRETIONS were collected from around the bovine cervical os using a vaginal speculum and spatula. (It would have been better to use secretions taken from the cervix itself; but such samples were too small for the technique available.) All samples were then reduced to a constant solid content of 0·14 per cent by dispersing in water and clearing in a centrifuge for one hour at about 7,000 *g*. Absorption curves, determined between 200 and 400 mμ, in general showed a maximum at about 273 mμ and a minimum at about 259 mμ.

In view of relationships recently found[1] between the flow properties of these secretions and physiological conditions, the first aim of the present work was to look for similar relationships with the absorption curves. Samples from normal animals during the œstrous cycle and in pregnancy were examined, and also similar types of secretion found in a few heifers already undergoing treatment with mixtures of œstrogen and progesterone. Measurements of the difference between the extinction coefficients at the maximum and at the minimum were taken. This quantity was considered to be more characteristic of the sample than the dimensionless ratio of the two extinction coefficients, since it is less dependent upon scattering and 'general absorption'. Since it has not yet proved possible always to obtain optically clear samples, results showing particularly high 'general absorption' were discarded. The accompanying figure gives a summary of preliminary results on twenty-nine animals.



$K_{max.}$ and $K_{min.}$: extinction coefficients at the maxima and minima on the absorption curves. Arrows represent average values. Broken lines represent standard deviations. Hormone treatment *A*: implants of tablets 30 × 100 mgm. progesterone; 15 × 100 mgm. stilbœstrol. Hormone treatment *B*: injections of 70 mgm. progesterone, 0·5 mgm. hexœstrol per day

In the figure, distinct differences in the average values and distributions of $K_{max.}$–$K_{min.}$ are shown for the œstrous, diœstrous and pregnant types of secretion. Samples from animals in œstrus and which are also under treatment *B* are almost indistinguishable from those in natural œstrus; and secretions from animals undergoing treatment *A* group themselves between the diœstrous and pregnant samples. With the few animals tested so far, no relation has been found between the values of $K_{max.}$–$K_{min.}$ and the duration of pregnancy.

Due to some imperfection in the prism, the slit was open too wide at short wave-lengths. Presumably as a result of scattering, a region of apparent total absorption often appeared at about 215–235 mμ. It was noticed that the width of this region was likewise a function of the physiological condition of the animal, but it is not yet known what physical properties of the secretions this scattering is representing.

Through the courtesy of Dr. A. G. Ogston, I have been able to examine a few similarly prepared samples in his concentric-cylinder flow-birefringence apparatus[2]. Six samples from cows in œstrus showed no sign of birefringence. Of four diœstrous samples, three showed measurable angles of isocline. Six samples from pregnant animals all showed measurable angles.

No attempt has yet been made to interpret these results in terms of the molecular components of secretions; further work is in progress.

I wish to acknowledge the guidance of Dr. G. W. Scott Blair, head of the Physics Department, under whose direction this work was carried out. Thanks are also due to Dr. S. J. Folley for suggestions, and to Mr. D. S. Flux for allowing me to take secretions from animals undergoing hormone treatment in his experiments.

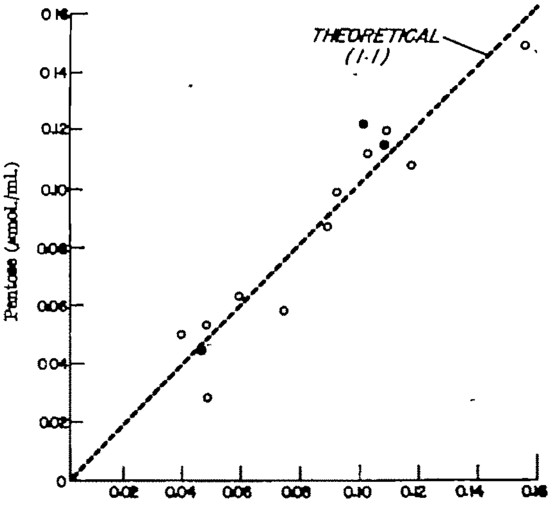
Occurrence of 4-Amino-5-imidazolecarboxamide as a Pentose Derivative

IT is becoming increasingly evident that 4-amino-5-imidazolecarboxamide occurs as a riboside and ribotide, and that these pentose derivatives are important intermediates in the biosynthesis of purines and their derivatives. Greenberg[1] has provided evidence that in the biosynthesis of inosinic acid a ribotide is formed before the completion of the purine ring occurs. Schulman and Buchanan[2] showed that the specific activity of isolated inosinate was considerably greater than that of inosine or hypoxanthine after incubation of labelled 4-amino-5-imidazolecarboxamide with pigeon liver extracts, and that inosinate could undergo an exchange reaction at the 2 position involving ribotide of the carboxamide and formate. Greenberg[3,4] has isolated both the riboside and ribotide of 4-amino-5-imidazolecarboxamide from culture fluids of *Escherichia coli* under conditions of sulphonamide bacteriostasis[5]. The enzymatic conversion of the carboxamide to its deoxyriboside has been reported with *Lactobacillus*[6] and *E. coli*[7].

In analysing various *Escherichia coli* systems where 4-amino-5-imidazolecarboxamide is known to accumulate in high concentrations, we have found further evidence for the existence of this compound as a pentose derivative. The majority of the experiments were performed with a purine-requiring mutant of *E. coli*, *B*-96, which accumulates the carboxamide by virtue of a genetic impairment in its conversion to purines[8].

The first evidence which suggests that 4-amino-5-imidazolecarboxamide accumulates as a riboside (or ribotide) in *E. coli* systems is the concomitant occurrence of a pentose, as measured by the orcinol reaction, with the occurrence of the carboxamide as measured by the Bratton–Marshall[9] reaction for diazotizable amines. The results were collected from a wide number and variety of independent experiments and plotted as shown in the graph. Most of the points were obtained from analyses of culture fluids of the purine-requiring mutant, *B*-96, grown under various conditions; a few were obtained from cultures of the wild-type parent strain grown under various conditions of sulphonamide bacteriostasis.



Correlation of pentose (calculated as ribose) and 4-amino-5-imidazolecarboxamide. Open circles (○) derived from *E. coli* mutant, *B*-96, and closed circles (●) derived from parent wild-type *E. coli* *B* under conditions of sulphonamide bacteriostasis

As can be seen in the graph, the points obtained show a definite correlation with the theoretical line for a 1 : 1 molar ratio between 4-amino-5-imidazolecarboxamide and pentose calculated as ribose. Best correlations were obtained from 18–24 hr. cultures. Earlier analyses could not be made because the glucose present in the synthetic inorganic salts–glucose (0·2 per cent) media interfered with the pentose determination. In later cultures, the glucose either disappeared entirely or minor residuals could be adjusted for by the method of Drury[10].

The second evidence is provided by the chromatographic separation of two distinct non-acetylatable diazotizable amines from the culture fluid of the purineless mutant. Culture fluids of the mutant were obtained by centrifugation and run on ascending paper chromatograms with *n*-butanol : diethylene glycol : water (4 : 4 : 1). Examination of the dried paper under ultra-violet light revealed two spots at R_F 0·12 and 0·31. The entire sheet was cut into horizontal strips corresponding in width to an R_F value of 0·05. These were individually eluted with 0·1 *N* hydrochloric acid at 37° C. for 18 hr. Determination of diazotizable amine in the eluates revealed two areas of concentration corresponding to the spots revealed. Synthetic 4-amino-5-imidazolecarboxamide, as the hydrochloride, when similarly treated, gave a single spot at R_F 0·33. The results of a typical experiment are shown in the table.

PAPER CHROMATOGRAPHIC DISTRIBUTION OF DIAZOTIZABLE AMINES

R_F range	Percentage of total amine Mutant *B*-96	Percentage of total amine AICA*
0·00–0·05	3·5	0·7
0·05–0·10	25·7	1·0
0·10–0·15	10·1	5·1
0·15–0·20	5·2	7·2
0·20–0·25	8·1	11·2
0·25–0·30	12·0	16·3
0·30–0·35	36·0	56·0
0·35–0·40	1·5	2·4
0·40–1·00	0·0	0 0

* Recovery of synthetic 4-amino-5-imidazolecarboxamide hydrochloride added to supernatant of wild-type *E. coli B* culture.

The two separate amines, so obtained, behaved identically with the synthetic carboxamide in terms of coupling-rate after diazotization, colour of diazo dye, spectrum of the dye (absorption peaks at 316 and 540 mμ) and ratio of optical density of the diazo dye at 540 mμ to untreated eluates at 265 mμ. The ultra-violet absorption spectra of the synthetic and the faster-moving material were identical. (E_m at 267 (max.) = 11·8 × 10^3.) The absorption spectrum of the material with the slower R_F, however, corresponded with that of the others only at wave-lengths greater than 260 mμ. At wave-lengths less than 260 mμ a distinct displacement was found in the direction of a greater absorption by the slower-moving amine. For example, the absorption was 30 per cent greater at 240 and 250 mμ.

An examination of the eluates for pentose showed that 57 per cent of the total pentose present in the original supernatant was associated with the slower-moving amine, the remainder being at the level of the faster-moving amine. Since free ribose, when similarly chromatographed, concentrates at an R_F of 0·37, the latter could represent free ribose resulting from nucleoside cleavage. Chromatographic analysis of 4-amino-5-imidazolecarboxamide and its respective derivatives by Greenberg[4,11] indicates that the amine with the low R_F as described here could indeed be the ribotide, and that with the higher R_F value could represent the free base or the riboside or a mixture of both. The latter may have resulted from nucleosidase and/or phosphatase activities of the organism. This was strengthened by an additional experiment based on one reported by Greenberg[3,4]. When the amine in the low R_F eluate is subjected to acid hydrolysis, it is converted to a single amine which becomes concentrated entirely at the higher R_F-level.

The evidence presented here concerning the natural occurrence of 4-amino-5-imidazolecarboxamide as a nucleoside or nucleotide serves to strengthen further the concept that, in the biosynthesis of purine derivatives, pentose addition occurs prior to ring closure of the purine nucleus[1].

This research has been aided by a grant from the National Foundation for Infantile Paralysis.

An Indirect Polarographic Determination of Calcium

In order to overcome difficulties associated with the direct polarographic determination of calcium, Cohn and Kolthoff[1] employed an indirect approach using picrolonic acid. We have found, however, that chloranilic acid, previously used by Tyner[2] for the colorimetric estimation of calcium, is preferable to picrolonic acid in that it is more sensitive and requires a much shorter reaction-time.

Calcium reacts quantitatively with chloranilic acid, precipitating calcium chloranilate. In solutions neutral to Congo red, the reaction is complete within ten minutes. Calcium may be estimated, without removing the precipitate, by adjusting the pH of the solution to 4·5 with universal buffer[3], measuring the polarographic diffusion current of the residual chloranilic acid, and referring the value obtained to a calibration curve. Calcium may thus be determined within a concentration range of $1{\cdot}3 \times 10^{-4}$–$1{\cdot}2 \times 10^{-3}$ M with a maximum error of approximately ± 3 per cent. When analysing solutions containing an unknown amount of calcium, it is first of all necessary to estimate the calcium roughly by adding 0·5 ml. of the solution to 7·5 ml. of 2×10^{-3} chloranilic acid: the reagent should not be decolorized within ten minutes after the addition of the solution.

The determination cannot be carried out in the presence of cobalt, lead, zinc, manganese, cadmium, nickel, aluminium, copper and silver, since these ions precipitate the reagent. Sodium, potassium, ammonium, magnesium, ferric and mercuric ions do not cause precipitation; but the latter two should not be present in concentrations greater than $4{\cdot}8 \times 10^{-4}$ M and $5{\cdot}9 \times 10^{-4}$ M respectively. Magnesium does not interfere in concentrations lower than $2{\cdot}4 \times 10^{-3}$ M, nor do lithium, barium and chromium when their concentrations are less than $5{\cdot}9 \times 10^{-4}$ M. Strontium does not affect the determination if present in concentrations up to $3{\cdot}6 \times 10^{-4}$ M.

Calcium has been determined in the ash of blood serum and of milk with an accuracy of approximately ± 3 per cent. Recovery experiments and parallel determinations using the oxalate–potassium permanganate method indicate that polarography yields more reliable results. The procedure is not only rapid but is also unaffected by the presence of magnesium and iron in concentrations commonly found in biological materials. Thus calcium can be estimated in blood serum showing marked hæmolysis.

Details of the method will be published elsewhere.

We are indebted to Mr. G. Loftus Hills for suggesting this research problem and to the Dairy Section of the Commonwealth Scientific and Industrial Research Organization for financial assistance.

Mesomeric Effect of the Sulphonic Acid Group

INFORMATION about the effect of the aromatically bonded sulphonic group has been obtained by studying its influence on the reactivity of other substituents of the same molecule. A suitable way is the measurement of acidity constants of phenols, anilinium ions and aromatic carbonic acids. Earlier investigations on these constants for naphthylaminesulphonic acids[1] and naphtholsulphonic acids[2] showed the existence of an electrostatic effect which is due to the dipolar structure and the negative charge of the SO_3^- substituent. A. Bryson, who investigated the naphthylamines, points out that the differences in the pK-values provide evidence for the conjugative interaction of the sulphonate ion and the aromatic ring. I was unable to extend this conclusion to the naphtholsulphonic acids.

I therefore investigated derivatives of benzenesulphonic acids and evaluated the measured acidity constants with Hammett's equation for *m*- and *p*-substituted benzenes. The accompanying table shows the results of the potentiometric determination of the pK-values in water at an ionic strength

ACIDITY CONSTANTS AND σ-VALUES
(ionic strength $\mu = 0{\cdot}10$; 25·0° C.)

	pK_1	pK_2	σ_m-SO_3^-	σ_p-SO_3^-
Aniline	4·71			
Metanilic acid		3·65	+ 0·39	
Sulphanilic acid		3·12		+ 0·58
Phenol	9·86			
m-Phenolsulphonic acid		9·07	+ 0·39	
p-Phenolsulphonic acid		8·70		+ 0·58
Benzoic acid	4·09			
m-Sulphobenzoic acid		3·78	+ 0·31	
p-Sulphobenzoic acid		3·72		+ 0·37

$\mu = 0{\cdot}10$ and the σ-values calculated with these constants.

These σ-values of the *m*- and *p*-sulphonic group may be compared with those of the other substituents mentioned in the literature. From the table it is apparent that the effect of the *p*-SO_3^- group is not accurately described by a single σ-value. The constant for *p*-sulphobenzoic acid is 0·21 smaller than the values of the constants for sulphanilic acid and *p*-phenolsulphonic acid. Comparable differences have been observed for *p*-NO_2 (0·49)[3], *p*-CH_3CO (0·44)[4], *p*-CN (0·34)[5] and *p*-CH_3SO_2 (0·42 and 0·26, respectively)[4,6]. By analogy with the interpretation for these substituents, we conclude that there is a conjugative effect in the sulphonic ions, too, and that the sulphur atom in sulphonic acids is capable of extending its octet to a decet (or dodecet) structure.

There is a peculiarity of the σ-constants for *m*- and *p*-sulphonic groups. So far as I know, this is the first negatively charged substituent for which σ-values for several equilibria have been calculated. All other substituents have a net charge of zero: only one of the groups investigated has a positive charge, namely, the trimethylammonium ion studied by Roberts and co-workers[7]. The pK_2-values shown in the table relate to the ionization of a second proton of the molecule (the first, more acidic proton refers to the ionization of the SO_3H group). Therefore the acidity constants of these benzene sulphonic acid derivatives show a different kind of dependence on changes in ionic strength from the unsubstituted compounds phenol, anilinium ion and benzoic acid. This explains why the σ-values for *m*- and *p*-SO_3^- (but not for electrically neutral groups) depend in a high degree on the ionic strength. The σ-values calculated from acidity constants at ionic strength $\mu = 0{\cdot}01$ and 0·001 are smaller than those shown in the table. The observed differences of σ-values for the *p*-SO_3^- group are important evidence of the mesomeric effect. The acidity constants at low ionic strengths were measured spectrophotometrically in the range 220–255 mμ. A description of the experimental procedure as well as a detailed discussion of the results will be published later in *Helvetica Chimica Acta*.

Gravity Survey in the Congo

THE Service de Météorologie et de Géophysique of the Belgian Congo has started a basic survey of gravity stations, in order to supply a fundamental network to workers engaged in more detailed measurements.

The link with European observatories has been provided by two important pieces of work; the first by Madame Duclaux and M. Martin from Paris, who in 1950 established in this territory nine stations carefully surveyed with a North American gravity meter; the second by M. Sanders, from Uccle Observatory, who in 1951 measured gravity at three of those nine stations by a refined technique using a modified Von Sterneck pendulum instrument. The values found by these workers have been published elsewhere; they are in excellent agreement.

We have used these nine stations to calibrate our North American gravity meter and proceeded to establish the first part of our basic network. This consists of twenty-seven aerodromes where repeated measurements have been made along relatively short overlapping circuits, enabling the observations to be made generally at two or three stations in one or at most two days before returning to base. The survey took place between July and September 1952.

The gravimeter has been fitted with an improved dial, and was transported by air in an air-tight container in which the pressure was maintained at the value it would have at the next station along the circuit. After a short rest, readings were taken by two different procedures: first, by adjusting and reading the dial several times when the index was on the centre of the micrometric scale; secondly, by adjusting and reading the dial for various settings on the micrometric scale. This second method amounts really to determining a very small correction for errors in levelling.

With the above precautions added to the usual technique, it has been possible to attain remarkable consistency in the measurements. The provisional results, in which no corrections for sun and moon tidal variations have been made yet, are given in the accompanying table. A detailed account of the work, and corrected values, will be published shortly.

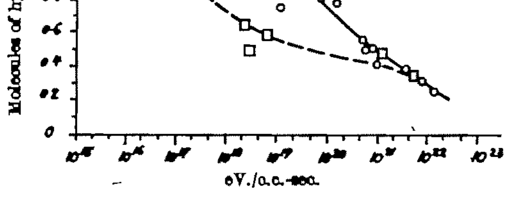
Formation of Hydrogen Peroxide in Water by 1-MeV. Protons

EXPERIMENTS using monoenergetic protons from a Van de Graaff accelerator have been carried out on the formation of hydrogen peroxide in water. The irradiation chamber was of 'Pyrex' glass, including a thin window through which the protons entered. The total volume of water irradiated was 0·4 c.c.; however, the irradiation volume was only 6·9 × 10^{-4} c.c., because of the short range of the protons in the sample. The absolute amount of hydrogen peroxide which is formed does not change when the total amount of water is varied from 0·2 to 0·5 c.c. The chemical determinations were made with a Beckman model *B* spectrophotometer at 3500 A. utilizing the iodide method suggested by Ghormley[1]; this method is capable of measuring 2 × 10^{16} molecules of hydrogen peroxide per litre. The water was freshly prepared by redistillation from a permanganate solution with a 'Pyrex' still.

For each determination the total energy input into the water was about 10^{18} eV. At the rate of 3·3 × 10^{20} eV./c.c.–sec., the amount of hydrogen peroxide formed was linear with dose up to a total input of 10^{19} eV.; at the rate 3·5 × 10^{18} eV./c.c.-sec., the amount of hydrogen peroxide formed was linear with dose at least to 5 × 10^{18} eV. All the rates of energy input refer to the irradiation volume of 6·9 × 10^{-4} c.c.

The efficiency of the formation of hydrogen peroxide by 0·95-MeV. protons is found to be highly dependent upon the rate of energy input. When the dose-rate is varied from 2 × 10^{16} eV./c.c.-sec. to 10^{22} eV./c.c.-sec. with air-saturated water, the efficiency decreases from 2·0 molecules hydrogen peroxide/100 eV. to 0·3 molecule hydrogen peroxide/100 eV., as shown in the graph. The results also show that the exclusion of air in and over the water by a helium atmosphere (less than 0·05 per cent oxygen) reduces the efficiency of formation of hydrogen peroxide by a factor of two at 10^{17} eV./c.c.-sec., but at 10^{21} eV./c.c.-sec. the efficiency is not changed by the absence of dissolved air in the water.

The observations suggest the following conclusions: (1) The formation (or the formation and destruction) of hydrogen peroxide in water is dependent upon the rate of energy dissipation per unit volume of the incident radiation. (2) 1-MeV. protons are intermediate in behaviour between alpha-particles and X-rays, as one might expect from the comparative linear ion densities. In oxygen-free water, alpha-particles and protons produce hydrogen peroxide; however, the presence of dissolved oxygen increases the efficiency of hydrogen peroxide formation with protons except with very high dose-rates. (3) It seems likely that the efficiency of formation of hydrogen peroxide does not continue to increase as the dose-rate is decreased below 10^{17} eV./c.c.-sec. For example, in the region of 5 × 10^{15} eV./c.c.-sec., Bonet-Maury[2] found that the efficiency of production of hydrogen peroxide by 13-kV. X-rays with dissolved air in the water becomes greater with increasing dose-rate. These two results suggest that a maximum in the efficiency of production of hydrogen peroxide may exist in the region of 10^{16}–10^{17} eV./c.c.-sec., the exact position of the maximum depending on the linear ion density of the ionizing particles.



Yield of hydrogen peroxide in water vs. the rate of energy loss per unit volume by protons

Stability and Settling of Dispersions of Carbon in Organic Media

IN an investigation of the action of detergent additives in engine lubricating oils, the sedimentation behaviour of suspensions of carbon black in a wide range of organic media has been studied. Suspensions were prepared by dispersing 0·5 gm. of carbon black ('Micronex') in 25 ml. of the liquid by means of 19 kc./s. ultrasonic vibration. The sedimentation behaviour of such systems falls into two distinct classes, depending on the detergent properties of the liquid.

Class (1) includes the majority of pure organic liquids and solutions of weakly detergent additives in hydrocarbons, and is characterized by a settling process which involves the formation of a sharply defined interface between supernatant clear liquid and opaque dispersion. The sedimentation process follows the equation:

$$\ln\left[(V_t - V_\infty)/(V_0 - V_\infty)\right] = -Kt, \qquad (1)$$

where V_0 is the initial volume of the dispersion, V_t is the volume occupied by suspended material at time t, V_∞ is the final volume occupied by the suspension, and K is a constant the value of which is dependent on the nature of the liquid and may be used to assess its detergent properties. It follows from equation (1) that the particle velocity during sedimentation is a function of the shape of the vessel, and thus this sedimentation process differs radically from conventional concepts of settling of particles in liquids. The settling is complete in times of the order of 24 hr., and the final volume occupied by the sediment is of the order of 10–15 ml.

Class (2) comprises systems in which the entire liquid phase is always uniformly opaque. In some of these systems a deposit of sediment may gradually settle to the bottom of the vessel. As the deposit accumulates, so the opacity of the supernatant suspension decreases. The times involved are of the order of several months, and the final volume occupied by the sediment is only of the order of 1 ml. With other solutions, including those of the most strongly detergent lubricating oil additives, and also with certain very polar organic liquids such as nitrobenzene and aniline, no sedimentation has been observed over periods of many months.

The explanation of these phenomena can be based on hindered aggregation under Brownian motion of the particles[1]. In the systems of class (1) it is postulated that aggregation results in the formation of a chain-and-scaffolding structure of particles and aggregates. This lattice-like structure extends throughout the entire volume of the dispersion, and traps suspension within voids. Continued aggregation of enmeshed but suspended particles on to the network causes its collapse through overweight. The collapsing network thus gives rise to the sharp interface, since the probability of an individual particle escaping from a void into the supernatant liquid is very small compared to its probability of aggregating on to the lattice during its motion towards the interface.

Consideration of the rate of diffusion of particles to the network under Brownian motion leads to equation (1) above, with

$$K = (kD/\overline{x^2}) \exp(-E/RT), \qquad (2)$$

where k is a constant dependent on the geometrical arrangement of particles and network, D is the diffusion coefficient for the particles, $\overline{x^2}$ the mean square distance of a particle from the network, and E is the magnitude of an energy barrier to aggregation.

The energy barrier arises from the work involved in expelling liquid, against surface forces, from between the coagulating particles.

Thus:

$$K = (kD/\overline{x^2}) \exp(-X\rho\gamma/RT), \qquad (3)$$

where ρ is the density of the liquid, γ the interfacial tension and X a constant dependent on the volume of liquid expelled. If $\ln(kD/\overline{x^2})$ is small compared to $\ln K$, equation (3) predicts that a plot of $\ln K$ against $\rho\gamma$ for different liquids should be a straight line with a negative slope. Experiments with a wide range of pure organic liquids and binary mixtures have confirmed that this relation holds when values of γ for the liquid-air interface are used[2].

Solutions of surface-active additives follow equation (1), but cannot be correlated by equation (3) because it is not possible to state what values of ρ and γ should be used for the material adsorbed at the carbon – liquid interface. It is possible that the persistence of the network structure is responsible for the large final sediment volumes exhibited by these systems, which are many times the 'dry' volume of the carbon.

In the systems of class (2) the energy barrier to aggregation may be so large that significant aggregation can never take place. This is confirmed by the large value of ($\rho\gamma$) for nitrobenzene and aniline. On the other hand, with less stable systems sedimentation occurs, but the rate of growth of aggregates is not sufficient to give rise to the lattice network. The aggregates are able to settle unhindered under Stokes's law.

Electrical phenomena at the carbon – liquid interface contribute to the energy barrier to aggregation. Electrophoresis, electro-osmosis and sedimentation potentials have been demonstrated in the systems[3]. If a stable suspension which exhibits electrophoresis of the particles to the anode is mixed with a stable suspension which exhibits cataphoresis, then a very rapid mutual coagulation takes place.

A Double-Beam System for Infra-Red Spectrometers employing Rotating Twin Cells

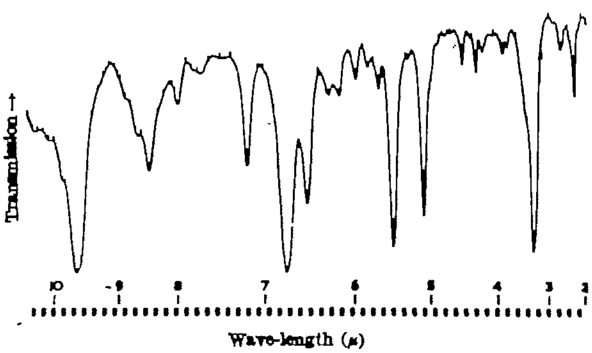
THE desirability of using direct-ratio instruments for the recording of infra-red spectra is immediately obvious when one considers the labour involved in measuring energy curves with the customary 'cell in—cell out' technique, and then carrying out the corresponding point-by-point division necessary to obtain a spectrum of percentage transmission versus wave-length. There are also the attendant difficulties arising from possible variations in source intensity or in atmospheric absorption between two consecutive runs. An instrument which performs these functions automatically must be capable of viewing the radiant energy passing through both the sample and standard cells simultaneously.

These requirements have been satisfactorily fulfilled by a number of double-beam instruments described in the literature. However, it is true to say that, in general, the systems involved are either of special design in costly commercial apparatus, or else have entailed very expensive optical and electronic modification of single-beam instruments. A previous suggestion for a simple instrument has been published but was later withdrawn[1].

A simple double-beam attachment for a standard single-beam instrument (Perkin Elmer Model 12C) can be built at little cost. No optical modification is needed and a minimum of additional electronic equipment is required for the existing set-up.

The method employed is essentially an alternating beam system used in conjunction with a voltage ratio recorder. The beam-splitting system consists of a demountable twin cell arranged as a rotating sector wheel of which two quadrants are the control and sample cells, the others forming metal shutters so that the output to the monochromator has the following sequence: I_0 beam through control cell (1/26 sec.), blocked by shutter (1/26 sec.), I beam through sample cell (1/26 sec.), blocked by shutter (1/26 sec.), thus providing an output at 13 c./sec. at the detector. The twin cell unit is conveniently mounted in front of the entrance slit of the monochromator and is the only addition to the present optical system. The cell unit is driven through bevel gears from the shaft of a synchronous contactor arranged to provide signal rectification and separation, zero shift of the I beam and test signals of known voltage for calibration purposes.

In order to provide sufficient output to energize the low-resistance slide-wire of the recorder, an additional power amplifier unit has been included. The existing Brown recorder has been used with an



additional slide-wire to permit its use as a ratio recorder without impairing its use for single-beam operation. The Perkin Elmer string-slit drive has also been retained and provides a sufficiently constant energy-level for the system which is not dependent on a strict control of the I_1 signal.

Finally, the whole system has been so arranged that a return to single-beam working may be made immediately by removing the twin cell unit and isolating the additional electronic equipment by a simple switch.

Although the system has not been long in operation, satisfactory results have been obtained comparable with those given by the conventional commercial double-beam instruments. As an example, the instrument record of the infra-red spectrum of benzene in carbon tetrachloride solution measured in a 100-μ cell over the wave-length range 2–10 μ is reproduced herewith. It will be noted that the sharp absorption bands in the 5–7-μ atmospheric water-vapour region are readily resolved.

Full details of this method, which may also be applied to visible and ultra-violet spectrometers, will be described elsewhere at a later date. We thank the President, Council and Director of the Research Association of British Paint, Colour and Varnish Manufacturers for permission to publish this communication; also Mr. E. W. M. Fawcett for his advice and guidance.

A Method for the Determination of the Approximate Surface Areas of Particulate Solids

A method I have devised for the determination of the approximate surface areas of particles involves the determination of the relationship between moisture content (v) and suction pressure (h). Graphical integration of this function gives the work done during withdrawal of water, and, provided the process is carried out isothermally, this work is equal to the increase in the surface free-energy of the water. Hence the increase in surface area of the water is given by:

$$\Delta A = \frac{1}{\gamma}\int h.dv,$$

where γ is the surface tension of water. Provided that the contact angle between water and the solid is zero, and that a sufficiently large suction can be applied, this area approximates very closely to that of the solid.

A method based on the same principle, but measuring the thermal energy liberated when a liquid surface surrounding a solid is destroyed adiabatically on immersion, has been developed by Harkins and Jura[1].

The very simple apparatus used for the new method is a slight modification of that described by Haines[2]. The solid is supported on a slate dust or sintered glass membrane sealed into a Buchner funnel, the stem of which is connected to a burette by means of a thick-walled rubber tube. The funnel and burette thus form the two limbs of a *U*-tube. The apparatus is filled with water so that the solid is just saturated, the water-levels in the burette and funnel being the same. Lowering the burette imposes a suction on the sample, and water is withdrawn, its volume being measured from the burette readings. The suction applied is given by the change in water-level. From the results obtained at successive increases in suction, the moisture content of the sample is plotted as a function of suction pressure. Graphical integration then permits calculation of surface area.

Glass spheres of measured sizes were mixed to give known surface areas of 1,800–15,000 sq. cm. per 100 gm.; their moisture content – suction pressure curves were determined and surface areas found from these.

Glass spheres grade	Area (cm.²/100 gm.)	Exp. values	Glass spheres grade	Area (cm.²/100 gm.)	Exp. values
6	1,830	1,650	8+12	5,920	6,480
		1,640			6,370
		1,700		7,590	7,490
		1,640			7,790
6+8	3,120	3,330	12	9,370	9,250
		3,350			10,010
8	4,140	3,960			9,860
		4,040			9,840
		4,170	12+16	11,900	11,720
		3,940			11,450
				14,400	13,410
					13,540
			16	15,000	14,630
					15,240
					14,940

These results were obtained with suctions up to 100 cm. of water, and with no temperature control. Greater accuracy can presumably be attained with more attention to detail, if so desired.

With the finer particles, accuracy has been increased by replacing the air–water interface by benzene–water, with a reduction of interfacial tension from 72·75 to 35·00 ergs per sq. cm. (at 20° C.).

It is hoped to extend the range of the method by working to higher suction pressures, using high-pressure equipment such as the pressure-plate apparatus of Richards[3].

The method may be useful to measure the breakdown of porous materials where the increase in area may be very small compared with the area of the fine pores, since by choosing suitable pressure limits the finer pores remain filled with water and are thus excluded from the area measurement.

D. Payne

Department of Agriculture,
University of Leeds. March 19.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER (qualified either in Science (physical or biological) or Mathematics, and with teaching experience) **IN THE DEPARTMENT OF EDUCATION**—The Registrar, University College of Wales, Aberystwyth (August 15).

SENIOR PHYSICIST (with experience in radiotherapy physics)—The Administrator and Secretary, University College Hospital, Gower Street, London, W.C.1 (August 23).

LECTURER IN ELECTRICAL ENGINEERING (with good honours degree in electrical engineering and industrial training and experience) at University College, Dundee—The Secretary, The University, St. Andrews (August 24).

KEEPER OF BIOLOGY (with degree in zoology, or botany, or Associate of the Museums Association, with specialization in these subjects)—The Director, City Museum, Park Row, Leeds 1 (August 28).

SCIENTISTS, Grade III (with good honours degree or equivalent qualification in a science subject, and preferably with a sound background in geology and chemistry) at Newcastle-upon-Tyne, Chester, Nottingham and Glasgow, for work on the preparation of detailed reports on the structure and physical and chemical properties of the coal seams covered by these laboratories (Ref. TT/664); **CHEMIST**, Scientist Grade II or III (with good honours degree or equivalent qualification, and preferably with some research or industrial experience of spectrographic techniques), at Nottingham, for work which will include spectrographic studies of the mineral matter associated with coal (Ref. TT/665); **PHYSICIST**, Scientist Grade II or III (with good honours degree, and preferably some research experience), at Sheffield, for work which will include studies of the optical properties of coal (Ref. TT/666); **SCIENTIFIC TECHNICAL OFFICER**, Grade II or Grade III (with good general training in chemistry, preferably to degree standard), at Newcastle-upon-Tyne (Ref. TT/667)—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting appropriate Ref. No. (August 29).

CHEMIST, Assistant Experimental Officer or Experimental Officer Grade (with Higher National Certificate in Chemistry or equivalent qualification) for mineral analysis of plants—The Secretary, East Malling Research Station, Maidstone, Kent (August 31).

PHYSICIST (with aptitude for mathematics and/or mechanical engineering) for theoretical and experimental work on the behaviour of textile fibres during their passage through machinery, and a **MATHEMATICIAN** (with some or all of the following qualities, (*a*) an aptitude for classical physics, (*b*) a mechanical mind, (*c*) an inclination towards statistics, for work mainly on the behaviour of textile fibres during their passage through machinery—The Director, South African Wool Textile Research Institute, Rhodes University, Grahamstown, South Africa (August 31).

EXPERIMENTAL OFFICER (Ref. F.139/53A), and an **ASSISTANT** (Scientific) (Ref. F.140/53A) for analytical work related to the Atomic Energy Production programme in establishments at Sellafield (Cumberland), Salwick and Capenhurst—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting appropriate Ref. No. (September 5).

LECTURER IN MECHANICAL ENGINEERING—The Registrar, The University, Sheffield (September 14).

CHAIR OF AERONAUTICAL ENGINEERING at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 15).

READER IN ANTHROPOLOGY at the London School of Economics and Political Science—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 17).

AERONAUTICAL OR MECHANICAL ENGINEER (Scientific Officer grade) (with first- or second-class honours degree or equivalent, preferably in aeronautical or mechanical engineering, and sound knowledge of mathematics) in a Ministry of Supply Experimental Establishment near Salisbury, for research, mainly on helicopters, covering investigations on performance, stability and control, operating techniques, and flight-test analysis and associated theoretical studies—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting O.392/53A.

ASSISTANT LECTURER (Grade B) **IN BIOLOGY**, in the Department of Chemistry and Applied Chemistry—The Principal, Royal Technical College, Salford 5.

ASSISTANT LECTURER (Grade B) **IN PHYSICS** (preferably with honours degree in physics, and experience or special interest in applied optics and spectroscopy)—The Principal, North Staffordshire Technical College, Stoke-on-Trent.

ASSISTANT PROFESSOR OF GEOLOGY—Dr. A. A. Duri, Dean, College of Arts and Science, Baghdad, Iraq.

CHEMIST/METALLURGIST (with honours degree in metallurgy or A.I.M. or equivalent, and practical laboratory experience) in the Ministry of Supply at Radway Green, Crewe, for investigation of metallurgical operations and their application to small arms ammunition production and development—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.313/53A.

ELECTRICAL ENGINEERS or **PHYSICISTS** (with H.S.C. (Science) or equivalent, and experience in electronics) for work on out-of-door instrumentation at Ministry of Supply Experimental Establishments near Southend and Carlisle and take charge of new electronic ballistic instruments and ancillary optical equipment as it is installed, and in conjunction with the designers, prove the equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.191/53A.

ENGINEERS and **PHYSICISTS** (with first- or second-class honours degree or equivalent in physics or electrical engineering) in the Electronics Division of the Atomic Energy Research Establishment, Harwell, for fundamental research on circuitry and the physics of nuclear radiation detectors, and devising and developing (often in collaboration with industry) electronic devices for Atomic Energy Project—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.196/53A.

PHYSICIST (Experimental Officer grade) (with H.S.C. (Science) or equivalent, and preferably with experience involving advanced metallographic techniques, and knowledge of high vacuum techniques and electronics) in a Ministry of Supply Research Establishment in S.E. London, to assist in work involving application of electron microscopy to explosives and metallurgical problems—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A 93/53A.

RIVER FLOODS IN GREAT BRITAIN

POTENTIALLY disastrous and fatal situations imposed upon man by Nature in her more violent and extreme moods largely include earthquakes, volcanoes, tornadoes, lightning, fog, tidal flooding and river flooding. Of these, fortunately, earthquake and volcanic activity can be discounted so far as Great Britain is concerned: tornadoes are experienced but rarely (the average is only one per year compared with 143 in America) and they are of limited intensity and duration; lightning is more frequent, but knowledge of the steps necessary to offset its danger is now fairly widespread. While these four phenomena can be quickly dismissed, the last three cannot, for these are the chief 'natural perils' for the inhabitants of these islands; and in each case a situation has arisen during the past twelve months with fatalities which have broken all previous records. The inversion fog which became established over the Thames basin during December 5–8, 1952, trapped four days emission from London factory and domestic chimneys, and the concentrated gaseous pollution plus the water fog was stated to be directly responsible for four thousand deaths and much damage to property. The tidal flooding on the east coast of England at the end of January 1953 caused nearly three hundred deaths and even greater damage to property, agricultural land and livestock; and the Exmoor river floods of August 15, 1952, drowned twenty-eight people, destroyed much of Lynmouth and swept away seventeen bridges.

All these events have naturally shocked the public conscience; but the public reaction has not been consistent. Relief funds were opened for the Lynmouth and east coast flood victims and substantial amounts collected. But no similar action was taken for the even greater London fog disaster. There was also a call for committees to investigate and report upon the problems of tidal flooding and smoke pollution (and active work is in progress). But the Lynmouth disaster was followed only by a local inquiry and did not stimulate any public demand for an investigation and report upon the general problem of river flooding, although this is more frequent in occurrence than either tidal flooding or fog disasters. That strong grounds exist for such an inquiry was made clear at a recent meeting of the Institution of Civil Engineers when the Lynmouth floods were under discussion. With the knowledge now at our disposal, much river flood damage and many fatalities could be avoided by precautionary measures. Without foresight, our increasing population will inevitably spread into potentially dangerous sites, and it can only be a matter of time before the Lynmouth disaster is exceeded.

River flooding occurs in two ways. It may be either periodic or episodic. There may be fairly regular flooding related to a repetitive regime in the life of the river. Winter rains or spring snow melt may produce annual floods, in which case the local inhabitants are fully aware of the need for adapting their way of life to that of the river. Flood-plain sites are avoided when buildings are erected, and bridges are adapted to maximum known flood conditions. The flood-plain of a maturely developed river may, however, be subject to longer-term inundations, and these have frequently caught unwary house builders and industrial operators, for example, in the Thames valley. Most of the major rivers in the British Isles have a long history of floods which, together with the geomorphological evidence, should provide adequate data for guidance in the proper use of the land. However, local authorities, architects and civil engineers have often failed to take these facts into consideration in the past.

The second type of flooding, exemplified by the Lynmouth disaster, may be regarded as episodic and is related to abnormally heavy storms. The effect of exceptional precipitation may be further intensified by immaturely dissected topography where water is concentrated in narrow valleys with torrential tracts —and devastating effects result. The tiny catchment area of 39 square miles south of Lynmouth yielded a flow in the river that has only been exceeded twice by the River Thames in the past seventy years, although the latter has a catchment area of 3,812 square miles. Flooding of this nature affects an area only at infrequent intervals, and any one incident may pass out of living memory before the next is experienced (Lynmouth's previous recorded flood was in 1796). The local inhabitants therefore may be lulled into a false sense of security as memories of the last serious flood fade into the past.

But over Great Britain as a whole, excessive rain which may lead to this type of flooding occurs with a frequency that is much greater than is generally realized. A fall of three inches of rain in one day is regarded as quite exceptional, and yet in the records in "British Rainfall" one finds dozens of cases from 1865 onwards, and falls of up to nine and a half inches in one day have been reported. Some of these falls have produced a series of historic floods, the most notable of which include the Moray disaster of August 1829; the Bodmin Moor episode of July 16, 1847, when all the bridges but three on the Camel and Inney Rivers were swept away; the Norwich floods of August 25, 1912, which caused great damage to the city; the River Lud (Lincolnshire) disaster of May 29, 1920, when twenty-three fatalities occurred and 1,250 people were rendered homeless; and the Vale of Conway floods of November 1925 when sixteen people were drowned. More recently, there have been the Afon Mawddach floods of May 1944 (not widely reported because of the war-time censorship on weather news); the south-east Scotland floods of August 12, 1948, which resulted in the loss of many bridges, much cattle and extensive damage to property; and finally the Exmoor disaster of August 15, 1952.

These are only some of the more notable episodes in a long and continual story of flooding. Countless other incidents have happened in the past; but with a smaller population fatalities have been fewer. The pressure of an increasing population upon available land space is already acute in these overcrowded islands, the number of towns and villages in valley situations is uncomfortably large and many potentially dangerous flood sites have already been built upon. Without guidance more will follow, and without precautionary measures it can only be a matter of time before another disaster of even greater magnitude than that at Lynmouth overtakes an unsuspecting community. In many areas future building activity, bridge construction, rail and road placements, etc., clearly should be related to the extreme river flood conditions, both periodic and episodic, likely to be experienced in the locality. A synthesis of information is called for from the meteorological records of the past century, earlier historical evidence and also the longer-term geomorphological record: from these data the hydraulic engineer can distinguish potentially dangerous areas. Particular attention should also be paid to those areas outside the spheres of influence of existing river boards—the Lyn, for example, was not a 'designated river'.

The situation touches so many professional interests that a *prima facie* case appears to exist for a committee of inquiry to investigate the problem, to ascertain existing responsibilities and their limitations, to recommend what precautionary measures of flood prevention and control through check dams, afforestation, etc., may be desirable, and to advise what legislative action, if any, should be taken.

KINDLY FRUITS

Science and Fruit

Edited by Prof. T. Wallace and R. W. Marsh. (Commemorating the Jubilee of the Long Ashton Research Station, 1903–1953.) Pp. xiii+308+31 plates. (Bristol: The University, 1953.) 30*s*. net.

LONG ASHTON, now celebrating its jubilee [see p. 273 of this issue], has become a world-famed centre for the scientific investigation of fruit products. Among these, cider reigns supreme. It is therefore fitting that this commemoration volume should deal largely with cider and that it should carry as frontispiece a characteristic portrait of that remarkable Westcountryman, Robert Neville Grenville, whose name was a watchword of agricultural progress at the opening of the twentieth century.

The Long Ashton Research Station arose, indeed, out of cider-making experiments which this genial 'Squire of Butleigh' began in 1893. These led in 1903 to the foundation of the National Fruit and Cider Institute at Long Ashton. This Institute commanded the support of the Board of Agriculture, the Bath and West Society, and the County Councils of Somerset, Devon, Gloucester, Monmouth, Hereford and Worcester. Within the next ten years the Institute became closely associated with the University of Bristol and developed into the Long Ashton Research Station.

The story of this institution, told in detail in the jubilee volume, is one of steady progress and expansion. Its vital importance to the nation became evident during the Second World War, when its staff reached a maximum size of eighty-five members. Brooke-Hunt wrote in 1903: "It is beginning as most things do which really last, in only a small way, but the potentialities are great; and it is hoped that its career may be one of increasing usefulness, not only in this generation but to others which are to follow". A glance at some of the activities of its first fifty years justifies fully these prophetic words.

In the first place, cider-making has altered out of all recognition since 1903, and has become a highly organized industry. This profound change is due mainly to activities at Long Ashton. In the related field of pomology, embracing the fruit industry in general, much progress has been made in the study of factors controlling vegetative growth, fruiting characters, and quality of fruit. Also in fruit breeding some useful new varieties of pears, plums and black currants have been produced at Long Ashton. As striking examples of work in plant nutrition, 'leaf scorch' has been traced to deficient potassium, and workers at Long Ashton have determined the roles of nitrogen, magnesium, iron, manganese, copper and zinc in English orchards.

Team-work conducted over many years has achieved valuable results in studies relating to plant pathology, entomology and the chemistry of insecticides. Indeed, Long Ashton has become a leading national centre of research on the control of insect pests and plant diseases, in particular through work on sprays and the study of spraying machines and equipment. Contributions to the knowledge of virus diseases of plants have led to the recognition of black currant 'reversion' and strawberry 'crinkle' as such diseases. Other work has been directed towards the domestic preservation of fruit and vegetables and the classification, breeding and control of osier willow varieties for use in basket-making.

Detailed information on these and other activities is given in a series of twenty-two documented contributions made by various authors to this interesting and well-edited volume. One set of papers affords a general review of the work conducted at Long Ashton between 1903 and 1953, and another deals with current work on such problems as plant-growth substances, plant micro-nutrients and recently introduced insecticides and fungicides. The volume also includes a record of names of scientific staff and other officers, Lord Rothschild's Jubilee Lecture, a preface by Captain D. M. Wills, and last but certainly not least a foreword by the Rt. Hon. Sir Winston Churchill, chancellor of the University of Bristol. The book has been admirably produced by that progressive University. The illustrations are well selected as records of historical and scientific development, although artistically one or two of the former show a somewhat large acreage of barren foreground. An index to the book would have been useful.

The historical illustrations of the Butleigh cider team and of various kinds of cider mills and presses give an indication of the antiquity of this ancient and honourable art of cider-making, taking the imagination back to the description in "Vinetum Britannicum" of 1691 by "*J. Worlidge*, Gent." of the "*Ingenio* or *Cider* Mill"; also to some observations of Mistress Celia Fiennes, about 1697, to the effect that "In most parts of Somersetshire . . . they are not curious in the Planting the best sort of fruite. . . . They are likewise as Careless when they make cider—they press all sorts of Apples together . . . They pound their apples, then lay fresh straw on the press, and on that a good lay off Pulp of the apples, then turne in the ends of the straw over it all round and lay fresh straw, then more apples to the top". Here is an early description of "putting up a reed cheese", figured in Plate 8 of the book under notice.

In spite of 'cider sickness', 'ropiness', 'acetification', and other 'disorders of cider', the best of the old-fashioned cidermen of Sutton Montis and other famous centres of bygone days were capable of wringing out a first-class product from their antiquated cider-wrings. Moreover, as T. A. Knight records in his "Treatise on the Culture of the Apple and Pear, and on the Manufacture of Cider and Perry", published at Ludlow in 1797, "the farmers and the peasantry . . . will drink it, and to a most extraordinary excess, when it is really acetous". Doubtless these old cider-drinkers saw a special significance in the pious hope reiterated week after week in the village church by each successive generation: "That it may please Thee to give and preserve to our use the kindly fruits of the earth, so as in due time we may enjoy them". That has been the virtual motto of the institution at Long Ashton throughout the past fifty years. JOHN READ

MOLECULAR THEORY OF FLUIDS

The Molecular Theory of Fluids

By Prof. Herbert S. Green. (Deformation and Flow: Monographs on the Rheological Behaviour of Natural and Synthetic Products.) Pp. viii+264. (Amsterdam: North-Holland Publishing Co., 1952.) 20 f.

THE theory of mechanical properties of materials which possess both elasticity and viscosity has received attention chiefly for the purpose of relating the behaviour of materials in bulk with a mathematical formulation of the rheological properties of a macroscopic element. But the theoretical problem of relating the behaviour of an element with the arrangement and intrinsic properties of the constituent molecules has proved more difficult and is by no means fully explored. In the case of liquids, the molecular theory cannot rely on the simplifying assumption of long-range order appropriate to crystalline solids, or on the assumption of long mean free paths as in the case of rare gases, and the problem is indeed a formidable one. Prof. H. S. Green's assessment of the present position in this field is valuable in directing attention to the mathematical difficulties which arise even when drastic simplifying assumptions are made concerning the properties of a single molecule, and to the important problems which remain unsolved. He shows how a single simplified theory has been developed to explain at least qualitatively all the main features of macroscopic behaviour in molecular terms.

For the most part, the discussion is restricted to non-polar fluids, the mutual molecular interactions being then represented by central forces. Equations expressing viscous and elastic properties, thermal conduction and self-diffusion rates and the conditions for condensation can then be constructed in terms of simple distribution functions. By this means those features of molecular flow are studied which do not depend on the structure of the molecules themselves. This restricted model of a fluid system could not be expected to provide a complete explanation of the observed phenomena, but it does provide a useful first approximation to real liquids. An indication is given of the diffusion effects to be expected when unlike molecules are present, and the consequences of asymmetric and polar molecules are briefly mentioned. The picture presented, of an assembly of molecules with well-defined positions and velocities, is a classical one, and quantum theoretical considerations are treated only in a final chapter. One feels that this important aspect of the problem could profitably have been discussed at greater length.

The large number of complicated mathematical equations are all well set out and concisely expressed in a specialized notation which is easy to use after a little practice. But the balance struck between the mathematical development of the argument and the physical description of the results does not always leave the reader with a very clear picture of their precise significance for real fluids. Some of the intermediate steps in mathematical arguments which could not be given fully might well have given place to more discussion, with more frequent references to original papers. The book is not an easy one to read, which is no doubt largely due to the inherent difficulty of the subject. It should be very stimulating to the serious student.

J. G. Oldroyd

IMPERFECTIONS IN METALS

Imperfections in Nearly Perfect Crystals

Symposium held at Pocono Manor, October 12–14, 1950. Editorial Committee: W. Shockley (chairman), J. H. Hollomon, R. Maurer, F. Seitz. Sponsored by the Committee on Solids, Division of Physical Sciences, the National Research Council. Pp. xii + 490. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1952.) 60*s.* net.

THERE can be only one opinion about this book—that it is, and will for some time remain, a standard work of reference on the subject of imperfections in crystals. It is a report on a conference held in the United States, and, as the list of names of the editorial committee suggests, a galaxy of talent has contributed to it. The list of contributors—twenty in all—is too extensive to be given here, but the standard is exemplified by the first chapter, in which Prof. F. Seitz gives an eminently readable general account of crystal imperfections. He introduces several terms, such as phonons and excitons, which will be new to many people but which will probably come into common use in the future.

The book is divided into four parts: the nature of imperfections; the role of imperfections in deformation; diffusion and related phenomena; and the properties and effects of external and internal surfaces. Seitz's chapter is by far the longest in the book; the rest of the contributors "dot the i's and cross the t's", as it were. As is usual in a symposium, the mode of treatment varies greatly; some chapters are descriptive and others are severely mathematical, but all bear the stamp of authority. The student of theoretical metallurgy is certain to find the book extremely valuable.

For this reason, I would suggest that the title of the book is unwise; it is pedantically correct, but is nevertheless misleading. In the first place, the practical aspects of the work described are almost entirely concerned with metals. It is true that the first chapter is written in general terms, and that there are two other chapters concerned with non-metals, but practically all the other authors make it quite clear that they considered the conference to be one on the metallic state. Secondly, why is the term "nearly perfect" included in the title? Is it usual, for example, to consider a cold-worked powder as nearly perfectly crystalline? Possibly it is nearly perfect, since the distortion rarely exceeds 0·1 per cent, but I maintain that the title of the book would not suggest immediately that such a subject is included.

This is an important point. The first contact the potential reader has with a book is in reading the title, and it would be a great pity if the title of this book were to cause it to be overlooked by the theoretical metallurgists of countries outside the United States.

H. Lipson

UNUSED LAND AND HUNGRY PEOPLE

Our Undeveloped World

By L. Dudley Stamp. Pp. 187. (London: Faber and Faber, Ltd., 1953.) 18*s.* net.

THE world's land surface is about 33 thousand million acres; only about 3 thousand million are cultivated: as the world's population is about 2·4 thousand million, this allows only 1·4 acres per head for both food and cash crops. If all this land were devoted to food crops and all gave English yields, a fairly satisfactory dietary would result; but some of the land is used for cash crops and most of it gives yields much lower than ours. Another 5¼ thousand million acres provides some sort of grazing and yields some meat and milk; but large numbers of the world's sheep and cattle furnish neither, and give only wool, hides and tallow. The world's average dietary remains poor.

It has long been the business of agricultural science and practice to seek ways of pushing the area of cultivated land into the grass regions or into the land wholly unused; the fact that 92 per cent of the land surface is uncultivated while millions of people go hungry has been a perpetual challenge that could not be ignored. Prof. Stamp has long studied these unused lands, and also those only partly developed: he summarized his results in the Patten Foundation Lectures given at the University of Indiana in 1950 which were published early in 1952 jointly by the Indiana University Press and the American Geographical Society, and are now re-issued with some additions and rearrangement in this British edition.

He begins with a discussion of the world population, its distribution and rate of increase in the different regions—pointing out incidentally that the increase is most rapid in the Americas, the crude birth-rate of the United States in 1947 being as high as that in India. He then gives a lucid account of the different regions of the world with special reference to their possible value for food production.

The wet tropical regions, in spite of the luxuriance of their forest vegetation, are not really very suitable: their soils are poor and lateritic; the native method of utilization is by shifting cultivation, which served so long as populations were low but is inapplicable when the numbers rise and increase the pressure on the land. As yet no very satisfactory substitute has been worked out, nor have the food crops been properly integrated with the cash crops, and until both sets of problems are solved there can be little further expansion of food production there. In the equatorial lands "the maps suggest that there are at least a couple of million square miles of under-developed or undeveloped land, but the difficulties of bringing them into use are enormous and are likely to remain enormous".

Nor do the tropical savannah regions hold out much greater hope. A considerable amount of scientific work is, however, being done in these regions, and further developments are still possible: the chief difficulties are likely to be the human ones of persuading the natives to accept the steady continuous labour necessary for modern agricultural systems instead of the broken periods with occasional outbursts of heavy work followed by longer stretches of comparative idleness, which suffice for the older methods. Nor does the author see much scope in the northern latitudes. Reference might have been made to the very interesting agricultural developments in Finland, described by Otto Valle in his book "Suomi", which is now available in English.

Prof. Stamp concludes that the middle latitudes offer the best scope for further expansion of food production, and he puts Canada, the United States and the Argentine as capable of considerable development. Undoubtedly they are, as recent events in the first two have shown; some curbing of output may indeed become necessary because of difficulties in selling the produce. But the fall in output from the Argentine also shows the difficulties brought about by political causes. The middle latitudes will probably always produce a physiologically adequate supply of food for their people; but the tropics also score in that they can supply oil seeds and alkaloidal beverages—cocoa, coffee and tea—to the world market.

Great areas of the middle latitudes and their warmer marginal regions suffer from inadequate water supplies, and this is one of the chief factors limiting food production in the world. A few pages only are devoted to this subject: fuller treatment would have been welcome. The author mentions a few irrigation schemes where the natural flow of the river is utilized along its natural course, but not the remarkable modern schemes where the river is actually turned back to the other side of the water-shed, like the Snowy River in Australia which naturally runs uselessly to the sea, but is now being tipped into the dry regions of the Murray system, or the Colorado River in the United States where the head waters are diverted from the Pacific side to the Atlantic side of the water-shed. This new power of diverting rivers may add considerably to the irrigation possibilities of the world—which are at present rather limited.

A later section of the book deals with "salvaging the land", to use the author's expression. As might be expected, he has a good deal to say on this subject and he emphasizes the need for proper land utilization surveys as the basis on which action should be taken. He recognizes the difficulties caused by the widespread poverty of the peasants who form the majority of the food producers of the world. "If," he says, "the millions of cultivators could be *given* fertilizers, and better implements and seed, and instructed in their proper use, they would get better crops with a better yield, build up their own strength and that of their families and their animals and have a surplus for sale—unless the net result of increased production would merely mean the increase of the family and a still larger number of mouths to feed." A simple calculation shows the colossal difficulty of making such a gift; and if made, its effect would certainly be to increase the population and leave the position pretty much as it is now. The author does not pursue this subject: instead he wisely confines himself to the methods by which the Old World can be salved and the New World preserved.

The book is very interesting and deserves study by all who are concerned with land utilization: it brings together much geographical detail not always easily accessible to the agriculturist, and it embodies personal observations by one who has travelled widely in the countries he is describing.

E. JOHN RUSSELL

TECHNIQUES OF RADIOCHEMISTRY

Modern Radiochemical Practice

By Dr. G. B. Cook and Dr. J. F. Duncan. Pp. xx+408+4 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1952.) 42*s*. net.

ONE of the most important of the benefits which have so far been derived from the development of atomic energy lies in the vastly increased availability of artificially radioactive materials; but although workers in many fields of pure and applied science have been quick to apply radioactive tracer methods to the solution of a wide range of problems, there is no doubt that such techniques could with profit find still more extensive application. It is difficult, too, to avoid a suspicion that some of those who turn to a Geiger counter where a previous generation would have used a chemical balance do not always appreciate fully the potentialities of the methods (nor, in some cases, the inherent pitfalls). The present volume, produced by two members of the staff of the Atomic Energy Research Establishment, Harwell, should go far in the provision of encouragement for the faint-hearted and authoritative guidance for those who wish to venture deeper into the borderland between chemistry and nuclear physics.

The greater part of the book is devoted to an exposition of the nuclear physical principles upon which radiochemistry is based: the laws of radioactive decay, the nature of the various nuclear radiations and the techniques for their measurement, and various aspects of radio-isotope production. Sources of errors in counting measurements are discussed at some length, and a chapter is included dealing with health precautions and laboratory design. The treatment is biased throughout towards the practical aspects of the subject, and this tendency is reinforced by the provision of detailed instructions for thirty typical radiochemical experiments, most of which can be performed with quite modest equipment. This outline of a practical course would make an ideal basis for inclusion in a university honours course in chemistry, and will clearly be of great value to those, already graduated, who wish to embark for the first time upon radiochemical work.

Although the more physical techniques are quite adequately covered, comparatively little is said about the associated chemical procedures; one would welcome, for example, a critical assessment of methods for carbon-14 assay and, perhaps, some discussion of the micro-methods which have been developed for the synthesis of compounds labelled with carbon-14. This would, perhaps, have been a better use for some of the forty pages that are devoted to a comprehensive "table of isotopes", information which is now so readily available elsewhere that such an extensive table scarcely seems necessary. A few minor blemishes have been noted: for example, inelastic scattering of neutrons can but rarely be an exothermic process (p. 208); increasing the time-constant can scarcely reduce the time of response of a rate-meter (p. 188); and the definitions given (p. 274) for "roentgen-equivalent-physical" and for "roentgen-equivalent-man" are distinctly misleading. None of these points, however, is really fundamental, and the general standard of accuracy is very high.

The production of the book is well up to the standards expected of the Oxford University Press, and the price, although higher than one might have wished, is certainly not unreasonable. The book should have an assured place in the growing literature of radiochemistry and should, moreover, be of considerable use to biologists and others interested in radioactive tracer methods. G. R. Martin

WAVES AND TIDES

Waves and Tides

By R. C. H. Russell and Comdr. D. H. Macmillan. Pp. 348+17 plates. (London: Hutchinson's Scientific and Technical Publications, 1952.) 25s. net.

THE connexion between waves and tides, clear enough to the physicist, is apparent also from the practical point of view. The effects of both concern the mariner and harbour engineer and are of interest to the seaside visitor, to whom this book is also addressed. Our knowledge of tides has reached a comparatively advanced stage, largely because of their regular nature and their dependence on known astronomical factors. Although the basic theory of waves was developed more than a century ago, reliable observations were scanty until the outbreak of the Second World War, owing to the difficulties of measuring such irregular phenomena, especially from a ship at sea. War requirements gave an impetus to the development of better measuring instruments, providing more observations which, in turn, have pointed to new theoretical problems.

In this book the subjects of waves and of tides have been treated separately by the two authors. Mr. R. C. H. Russell begins Part 1 by describing the characteristics of ocean waves and outlining the methods by which these have been determined. A concise account is given of the classical theory of waves in deep water, the changes which they undergo on approaching a shore, and the effects of reflexion, refraction and diffraction. The way in which waves are generated by wind has been the subject of recent researches and is still largely an unsolved problem. Turning from the waves themselves to their action in moving material and their effects on structures, the author includes much recent work, particularly on models. One is made aware of how many doubtful points and conflicting ideas there are in this field, and of the need for more research, especially of a fundamental character.

Commander D. H. Macmillan introduces Part 2 with a historical and descriptive account of tides, and then gives an account of the general features of the equilibrium theory. The next chapter is concerned largely with the natural and forced oscillations of bodies of water, and shows how the theory of such oscillations may be combined with the equilibrium theory to explain the features of tides as they actually occur. Subsequent chapters deal with more practical aspects, such as the prediction and recording of tides and tidal streams and the prospects of any large-scale use of tidal power. The short chapter on "Tides and the Weather" touches on a subject which has assumed greater topical interest since the book was published. The disturbance of tidal levels by storm surges and wind effects is one of the outstanding problems of tidal research to-day. An unfortunate number of misprints occur in the equations throughout Part 2, including two in the summary of formulæ on p. 334.

The authors have performed a valuable service in producing a book which presents the results of recent researches on waves and tides against a background of more firmly established knowledge. K. F. Bowden

FRESHWATER ALGÆ OF ILLINOIS

The Algæ of Illinois

By Lewis Hanford Tiffany and Max Edwin Britton. Pp. xiv+407. (Chicago: University of Chicago Press; London: Cambridge University Press, 1952.) 75s. net.

FRESHWATER Algæ have been intensively studied in many parts of the United States during the present century, and the rich and diverse character of this flora has been suitably epitomized in G. M. Smith's "Freshwater Algæ of the United States", now in its second edition. Tiffany and Britton's "Algæ of Illinois" deals with only a single State of the Union, covering an area larger than that of England, and takes the form of a flora with keys for the determination of genera and species and diagnoses and figures of the nearly 1,200 species so far recorded. It thus constitutes a work that is of considerable local value which will serve as a stimulus to those continuing with the task of exploration. For them some reference under each group to standard taxonomic works would have been helpful.

In such a local flora, dealing with a region which is still in many respects quite imperfectly explored, it is inevitable that the representation of different groups is unbalanced. Some, like the Oedogoniales and Zygnemales which have been specially studied in the area concerned, are represented by numerous species; but for others the records are meagre. Thus, large genera like *Chlamydomonas* and *Carteria* are each represented by only a single species, only three species of *Euastrum* and one of *Arthrodesmus* are recorded, while such a widespread epiphyte as *Chamaesiphon* is lacking. This inequality must, of course, detract from the value of the flora to workers in other areas and raises the question whether it is advisable to publish a manifestly incomplete record in so ambitious a form. It is to be regretted that the authors have omitted to give adequate habitat data for most species, since the value of a local flora to those working elsewhere depends largely on the geographical and ecological facts that can be gleaned from it.

The copious and for the most part clear illustrations, grouped in 108 plates, contribute much to the general usefulness of the work. A proportion of the figures are original, some of them of a somewhat diagrammatic type which is not always very informative, as, for example, those depicting *Phacotus lenticularis*. F. E. Fritsch

Le diamant

Histoire, cristallographie, performances esthétiques, taille, gisements, prospection, essai de reproduction synthétique, origine naturelle. Par Edmond Bruet. (Bibliothèque scientifique.) Pp. 256+8 plates. (Paris : Libr. Payot, 1952.) 800 francs.

As the sub-titles indicate, Edmond Bruet's new book, "Le diamant", makes no pretence to deal with the physical properties of the mineral, on which so much research has been carried out in recent years. The author is a geophysicist, and is primarily interested in the occurrence of diamond and in the art of diamond prospecting. The most extended treatment is given to the alluvial deposits in the forests of French Equatorial Africa, on which he writes from first-hand knowledge. Much of this will be new to British readers, since these fields, though they yield some 130,000 carats annually, only account for about 1 per cent of the total world production and are in consequence not much talked about. Recovery of diamond in this area is carried out by primitive methods, using native man-power to drill for samples, and crude jigs shaken by hand for washing and concentrating the gravel.

The more productive fields of South Africa, the Congo, etc., are also well described, and there are interesting chapters on the discovery of diamond in the Canyon Diabolo meteorite, and on the still unsolved mystery of its genesis in the rocks. On this subject, it is curious how little attention has been paid to the foreign minerals included in diamond (pyrope, zircon, enstatite, diopside, hæmatite, graphite, mica and quartz), which should provide more significant evidence than do the so-called 'associated' minerals as to the conditions existing when the diamond crystallized. The weakest chapter in the book is that in which methods for identifying the 'satellite' minerals of diamond are given. Here, for example, a list of ten minerals suggested as 'indicators' for use with heavy liquids cover the range 2·07–2·62 only, whereas not one of the minerals to be determined falls within this range.

On the whole, however, the book is interesting and informative ; it can be read with profit by anyone who is interested in the recovery of diamond either in theory or in practice. B. W. A.

Electrochemical Data

By Dr. B. E. Conway. Pp. xx+374. (Amsterdam and New York : Elsevier Publishing Co., Ltd. ; London : Cleaver-Hume Press, Ltd., 1952.) 55s.

In Vol. 2 of "Textbook of Electrochemistry", by Prof. G. Kortüm and Dr. J. O'M. Bockris, was included a chapter of 162 pages, entitled "Tables of Certain Physico-Chemical Properties", which was compiled by Dr. B. E. Conway. He has now expanded this chapter to about twice its original length and issued it as a separate book. In its present form it contains a great wealth of data, including much more than is suggested by the word 'electrochemical' in its narrower sense ; for example, it lists many of the properties of solvents, of melts at high temperatures, of double layers at surfaces, and of colloidal systems. References to original sources are included.

Judgment of such a compilation waits upon two criteria : the partly subjective one of what has been included and what omitted ; and the objective test of accuracy and reliability as shown in regular use. On the former, the selection seems to me to have been generally sound, though minor exceptions occur ; for example, the omission of any data on acid-base indicators, or the devotion of several pages to the Sörensen and Walbum buffer solutions without mention of the much more recent work of the National Bureau of Standards on the standardization of the pH scale or even of the British Standards Institution's 1950 publication on this subject. On the latter criterion it is difficult to express an opinion at this stage. Errors and misprints certainly do occur. Some of those noted in the earlier compilation (see *Nature*, 169, 982 ; 1952) have been corrected, but not all ; and there are others. Row and column headings have been reversed in Table II, 19 ; tables on pp. 56 and 59 list values for quantities A' and A_f respectively, without making it clear that they are essentially the same quantity and differ only because one is based on older values of the fundamental physical constants and the other on Birge's more recent ones ; no temperature is specified for the surface tension data in Table III, 57.

However, these criticisms are rather trivial in relation to the great mass of information provided. The volume will prove very useful not only to electrochemists but also to physical chemists generally.

J. C. Speakman

Einführung in die freie Geometrie ebener Kurven

Von Prof. Dr. Louis Locher-Ernst. (Elemente der Mathematik vom höheren Standpunkt aus, Band 1.) Pp. 88. (Basel : Verlag Birkhäuser, 1952.) 12.50 francs.

This little book is unique of its kind ; it gives an account of a branch of geometry hitherto treated only in rather inaccessible original papers. Although it was more than a hundred years ago that von Staudt and Möbius showed the possibility of studying plane curves by what may be called ultra-pure methods, without the use of co-ordinates, of any metrical considerations, and even of cross-ratios, these methods are still little known. The most important developments of the subjects were made by C. Juel, published in 1913–15 in a Danish scientific journal. Now at last Prof. L. Locher-Ernst has provided an accessible account of the subject, written in a style which makes it very easy to follow. Starting from a simple set of axioms and definitions, he obtains a great number of results ; for example, all possible forms of curves of the third order and third class. He also discusses double points, cusps and double tangents. It appears that many properties usually supposed to be typical of algebraic curves are really quite independent of algebraic or analytical considerations, since they are shared by the much wider class of curves considered here. There are 168 diagrams, 28 problems and an index of axioms and theorems. The book should be carefully studied by every geometer. H. T. H. Piaggio

Biological Staining Methods

By George T. Gurr. Fifth edition. Pp. vii+88+4 plates. (London : George T. Gurr, Ltd., 1952.) 5s.

In this, the fifth edition, the author has set out to cater for the investigator and technician who may have to discover appropriate methods for staining his biological materials. Formulæ and methods for staining a wide range of materials, involving the use of more than a hundred and fifty stains, are given, the results obtainable being illustrated by some colour photomicrographs. While a comprehensive general index is given at the end, the book would probably be improved by a short table of contents at the beginning. This valuable little manual may be commended both to general and specialist workers.

HIGHER TECHNOLOGICAL EDUCATION

By Prof. J. F. BAKER, O.B.E.

Department of Engineering, University of Cambridge

ONE of the liveliest discussions at the Congress of the Universities of the Commonwealth, held in Cambridge during July 13–17, arose at the meeting on "Higher Technological Education". The opening speakers were Prof. J. F. Baker, head of the Department of Engineering, Cambridge, Dr. K. Venkataraman, director, Department of Chemical Technology, University of Bombay, Prof. J. D. Baxter, director, New South Wales University of Technology, and Sir Roderick Hill, rector of the Imperial College of Science and Technology.

Prof. Baker gave a brief outline of the position of technology in the universities of the United Kingdom. He sketched the completely integrated activities of a typical department, the main interest and responsibility of which is the education of the undergraduate. The three-year undergraduate course concentrates on a grounding in fundamental science and in mathematics with the added discipline of dealing with particular problems in detail. Engineers have a philosophy of their own, and so the teaching must be in the hands of engineers. To remain engineers, teaching officers must engage in applied research, or consulting work of the right standing, which keeps them in intimate contact with industry. When their research has established their school as the leading authority in a particular field, it must be opened to postgraduate students returning after four or five years industrial experience for an intensive course of instruction. These mature men, who return with practical experience and a knowledge of industrial processes and techniques, are ripe for specialist instruction in the highly skilled operation of applying scientific method to the solution of industrial problems which they could not have appreciated in their undergraduate days. The domestic difficulties facing industry in freeing and paying for these men are great but not insurmountable. If they are not overcome the great pressure of engineering development will lead to a demand for lengthened courses for all undergraduates in which, at great expense, immature minds will be forced into moulds turning out, in the end, technicians and not technologists.

Dr. Venkataraman described the position in India. There the All-India Council for Technical Education, constituted in 1946, recognized the advantages of upgrading and enlarging existing institutions, and as a result large capital and recurring grants were made to fourteen departments or colleges of technology. In spite of this, technological institutions are faced with many problems, particularly the shortage of highly qualified and experienced teachers. The surprising statement was made that India turns out more chemical engineers than does Great Britain—and the output is in excess of the demand. The Ministry of Education has instituted a number of paid apprenticeships; but many more are required and industry must be persuaded to undertake this responsibility and also to support research in the universities, as Imperial Chemical Industries and other firms do in Great Britain. Dr. Venkataraman also made a plea for the encouragement of consulting work in the universities so that the staff can keep in touch with practice.

Prof. Baxter gave a most interesting account of the development and present state of the New South Wales University of Technology, the first of its kind in the British Commonwealth. Founded in 1949, it has already made rapid progress, having been fortunate in collecting a high-grade staff. There is, in the highly industrialized State of New South Wales, with its 65,000 technical students, an open road from the technical colleges to the University. The University of Technology decided, in 1951, to accept responsibility for part-time diploma courses. Two principles are followed: first, that a substantial amount of practical training is included in all courses; and second, that study of the humanities is not neglected. A typical arrangement is to devote to academic studies two twelve-week terms, with a two-week vacation between, leaving half the year free for supervised practical experience. In all courses time is devoted to such subjects as English, history and philosophy during the first two years of a course, while in the third and fourth years the student selects one of these subjects for further study. To the present courses in physics, chemistry and the three main branches of engineering are to be added in the future further specialized engineering courses and such subjects as textiles, rubber, plastics, food technology, industrial ceramics and building science.

Sir Roderick Hill turned to a more philosophical aspect of the problems posed by the advance of technology. He considered how we can escape the unregulated impact of applied science and asked what price the universities must pay for a partnership between it and the familiar academic disciplines. He feels it difficult to reconcile a vocational training with the broader education necessary to equip a man for life, but sees no reason why technological studies should not provide that rigorous intellectual discipline needed to train human excellence. Sir Roderick concluded with a plea that motives other than the need to survive must be put before young people; higher aspirations must be invoked.

The chairman, Dr. H. R. Raikes, vice-chancellor of the University of the Witwatersrand, before inviting general discussion, emphasized the importance of the following points: that technology should remain in the universities; that the courses should deal with fundamentals and be not too long; and that provision should be made for selected students to return eventually for postgraduate instruction.

Dr. A. E. Cameron, president, Nova Scotia Technical College, gave a picture of the position in Canada where eleven institutions cover almost all branches of engineering but naval architecture. The courses are of four years duration, the first two being devoted to science and the humanities and the last two to technology. However, such is the pressure of the science studies that the humanities and social science are assuming a minor role.

Dr. P. Dunsheath, London, stressed the vital necessity of close relations between industry and the universities, since industry is the controlling factor of modern life. Industry must learn what the universities do and how graduates can be introduced, particularly into small firms. The universities must learn to appreciate the nature and purpose of industry. He pointed out that the cessation of ear-marked grants throws an increased responsibility on the universities, since they must not neglect the needs of industry.

Prof. W. G. Sutton, Witwatersrand, claimed that in the technological field his university has the same aims as Cambridge. He feels that too much respect for research must not be encouraged among students of technology, but that postgraduate courses of instruction are desirable. He ended with a warning to New South Wales that South Africa from bitter experience knows the deficiencies of technological institutions as centres of higher education.

Prof. J. R. Daymond, Natal, in his turn claimed allegiance to the Cambridge aims. The University of Natal encourages students to graduate in science and then to read engineering for two further years. Prof. Daymund, taking more than twice the allowance of time given to other speakers, pleaded eloquently for a broader base to be given to the educational pyramid and for universities to resist the tendency to train in specific skills.

Prof. W. H. Hutt, Cape Town, who stressed the fact that he is not an engineer, expressed entire agreement with the views Prof. Baker expressed in opening the session, and summed up the discussion in the apt phrase, "Let the university teach 'why' and leave life to teach 'how' ".

ACADEMIC MOBILITY IN THE BRITISH COMMONWEALTH

By Sir CHARLES MORRIS

Vice-Chancellor, University of Leeds

At the recent Congress of Universities of the Commonwealth at Cambridge, at which more than eighty universities and university colleges were represented, there was a lively and most interesting discussion on "Academic Mobility in the Commonwealth". A previous Congress five years ago at Oxford had pressed for vigorous action to be taken to promote interchange of both senior and junior scholars between British countries; and following that Congress the United Kingdom Government made available through the British Council rather more than £30,000, so that a start could be made with the pilot scheme. Under this scheme, provision was made for three categories of scholars: very senior and distinguished people paying short visits on the invitation usually of several universities; professors and other established scholars on leave from their own universities for about a year; and junior scholars able to spend one or two years abroad at the beginning of their professional academic careers. It was clear from the discussion at the Congress that the minds of the universities in other Commonwealth countries have been working along the same lines, and a great deal of progress has been made in many countries.

The British Council scheme clearly covers only a part of the total movement between universities, but its role was recognized to be an extremely valuable one; the Congress showed itself particularly interested in the visits arranged in the first category mentioned above, namely, the short visits of very senior and distinguished people. In the meantime, it was obvious that there are some most desirable developments not covered or certainly not sufficiently covered by any of the arrangements in operation within the Commonwealth—in particular, movement between the universities and university colleges in the Colonial countries and the rest of the Commonwealth, and cross-movement between the 'peripheral' countries of the Commonwealth themselves. On the first point it was announced to the Congress that the United Kingdom Government has now made a fund available to enable similar arrangements to be made with the university institutions of the Colonial countries.

After a lively debate the Congress passed a resolution urging member universities to seek suitable opportunities for approaching their Governments with the request that they should contribute to "a co-operatively administered Commonwealth Interchange Fund". It need not be said that the Congress showed itself well aware of the high desirability of movement between the universities of British countries and of non-British countries, notably the countries of Western Europe and the United States. Tribute was paid especially to the success of the Fulbright scheme.

This was perhaps the most interesting instance of a resolution of the last Congress five years ago being actually brought into force. It was a significant instance. The zeal for promoting movement between universities has greatly increased in the past five years. Many speakers at the Cambridge meeting testified to the great value of interchange of undergraduates and young graduates; and a great deal of thought was given to the well-known problems involved in making it easier for members of the academic staff of a university in one country to move to a permanent appointment in another country. There was no kind of suggestion by anybody that too much importance was being attached to such movement or that the zeal for these developments was getting out of proportion. The only hesitant voices were from those who feared that movement between British and non-British universities might possibly suffer. There is no question that the Congress as a whole was most desirous that this should not be so.

THE UNIVERSITY OF LIVERPOOL (1903–53)

By Sir HENRY COHEN

Professor of Medicine, University of Liverpool

It is a happy circumstance that this year's meeting in Liverpool of the British Association for the Advancement of Science should coincide with the jubilee of the granting of the Charter to the University of Liverpool. For the story of the University's first fifty years is an enviable record both of notable men of science and of man's successful quest for knowledge. A University College had existed for twenty-one years before full university status was attained, and had been served by many impressive scientific figures, including Oliver Lodge who, after occupying the Lyon Jones chair of physics for nineteen years, had resigned to become the first principal of the University of Birmingham.

Thus at its birth the University already enjoyed a high scientific reputation and on its staff were at least two men of science who in their different fields were pre-eminent. The Liverpool School of Tropical Medicine, the oldest in the world, had been founded by the shipowner, Sir Alfred Jones, in 1898, to serve a pressing local need. Ronald Ross was its first lecturer and he had been appointed in 1902 to the Alfred Jones chair of tropical medicine. Two years later was established the diploma of tropical medicine. Ross's contributions to our knowledge of the malarial parasite, its anopheline transmission, and the effective prevention of malaria had led to a Nobel Prize, and he was in its early days the most renowned of the University's professors. His successors' impressive contributions in related fields reflect his stimulating personality—J. W. W. Stephens on malaria and black-water fever, and Warrington Yorke on the chemotherapy of malaria, trypanosomiasis and kala-azar. To-day the School's interest in chemotherapy continues, and the more fundamental processes which underlie the kidney and liver damage in malaria are being studied.

But since 1895, the George Holt professor of physiology had been Charles Scott Sherrington. He had been appointed to the chair when its earlier occupant, Frank Gotch, the eminent electrophysiologist, left Liverpool to succeed Burdon Sanderson at Oxford. Sherrington was to remain in Liverpool for eighteen years before he, too, left for Oxford. It was here that he published, in 1906, the "Integrative Action of the Nervous System", a classic which has been compared with Harvey's "De motu cordis" and Newton's "Principia". Here he laid those stable foundations of neurology which were to lead to the universal verdict that he was "the most profound student of the nervous system the world has yet known". Sherrington attracted many distinguished students to his Liverpool laboratory, including Harvey Cushing and Fröhlich, and many were trained here who later occupied with distinction chairs of physiology in Great Britain and abroad.

It was not only in tropical medicine that Liverpool's natural opportunities were seized. Among the most distinguished of early British oceanographers was William Herdman, who had occupied the Derby chair of natural history since 1881. He was an authority on the ascidians and gave to the School of Zoology a marine bias which profoundly influenced the work of two of his successors in the chair—W. J. Dakin, whose studies on the morphology of various marine animals and on the marine plankton earned him an international reputation, and J. H. Orton, whose life-long interest was the ecology of the sea-shore and who carried out fundamental work on the oyster. Herdman founded the Marine Biological Station in Port Erin, Isle of Man, both for research and for the training of students. More recently, a station has been opened on Lake Bala in North Wales to study the special problems connected with salmon and freshwater fish. Herdman's contribution to the University went beyond his academic gifts and influence. He and his wife endowed two chairs: in 1916 that of geology in memory of their son who was killed in action, with P. G. H. Boswell as the first occupant, and in 1919 that of oceanography, which Herdman himself occupied for a year. His successor was James Johnstone, a distinguished biologist and a profound thinker whose works reveal a man well ahead of his time in the philosophy and methodology of natural science. The character of this chair changed, however, in 1933 when it was accepted by J. Proudman, who had for fourteen years been professor of applied mathematics in the University. In his new chair he was able to continue his notable researches, in conjunction with the Tidal Institute, which have placed his name foremost among those connected with the theory of tides.

In the early years of this century, expanding interest in the application of the techniques of physics and chemistry to the study of biological phenomena led to the establishment a year before the Charter was granted of the first chair in biochemistry in Britain. Its first occupant was Benjamin Moore, whose contributions to the study of cell membranes was stimulated by his association with F. G. Donnan, but who had wider recognition for his forthright if unorthodox views on the origin of life. He founded, with Whitley, the *Biochemical Journal* which, before it was taken over by the Biochemical Society, was published in Liverpool.

There had been a chair of inorganic chemistry in University College since 1881. Its first holder was J. Campbell Brown, a sound teacher, but whose most fruitful contribution to the advance of chemistry was his bequest to the University for the endowment of a chair of industrial chemistry. This was occupied by T. P. Hilditch for twenty-five years (1926–51), during which time his investigations of neutral fats were so remarkably complete and authoritative that he has earned an unrivalled reputation in this field.

In the year in which the Charter was granted, Sir John Brunner endowed a chair in physical chemistry. This was held by F. G. Donnan for ten years before he left to succeed Sir William Ramsay at University College, London. He impressed his character and interests widely, and the influence of his work on membrane equilibria on Benjamin Moore's researches has earlier been noted. Donnan founded a strong research school. His pupils included A. J. Allmand of Kings, Hugh Taylor of Princeton, and F. A. Freeth of Imperial Chemical Industries. E. C. C. Baly, who had worked with Ramsay, went to Liverpool to succeed Campbell Brown in 1910. He was distinguished in spectroscopy and widely known for his mapping of the emission spectra of rare gases in Ramsay's laboratory. He was a man whose adventurous speculations were criticized adversely because they went beyond the then available techniques; but he stimulated others and has indirectly been responsible for much of our knowledge of photosynthesis and of plastics.

Organic chemistry remained without a chair until 1915, when an endowment enabled Robert Robinson to be appointed the first professor. Here he achieved the synthesis of tropanone and began his monumental work on alkaloids, which was the prelude to an outstandingly brilliant and fruitful contribution to his subject. He was succeeded in 1920 by Ian Heilbron. During his tenure of the chair, which he held until 1933, his major interests were his investigations on provitamin D, on sterols, and on vitamin A, which he was later to follow up with marked success.

In 1935 the University was singularly fortunate in securing James Chadwick to succeed L. R. Wilberforce in the chair of physics. Chadwick, the discoverer of the neutron and a Nobel Laureate, inaugurated work on nuclear physics which was to lead to dramatic developments and provide a notable contribution to our war effort. The present extensive building developments in nuclear physics stem directly from Chadwick's influence, though he returned to Cambridge in 1948 to become master of Gonville and Caius College.

It would be invidious to mention by name those who still serve the University. Many of them will leave an indelible mark on the history of science and a few will light lamps which will shine as brightly as any which illuminated the first half-century of the University's history. The territory now being covered is extensive. It includes the chemistry of natural products such as insecticides, fish poisons, and antibiotics; the synthesis of anthocyanins and new oxygen-heterocyclic compounds such as the chromonopyrones; studies on vitamin A, detoxication, and carotenoids, and the use of radioactive tracers in biogenesis; contributions to the theory of the solid state, metals and dielectrics; to differential geometry, relativity and cosmology; the phenomena of wakes and the compilation of mathematical tables; nuclear physics; endocrinology; and experimental zoology. Restricted space forbids reference to the related fields—engineering, medical, dental, veterinary and the social sciences—in which this University has made and continues to make a contribution of first-rate importance.

In this brief sketch of the outstanding scientific events in the history of science in the University of Liverpool during the past fifty years, it has been possible to mention only a tithe of the foremost figures and achievements. Also, these jottings have been "written by Time on the memory" of one man. Others may justifiably have painted a picture in different colours, light and perspective. Moreover, the solid contribution of many hundreds of a singularly able and loyal junior staff to the shape and stability of the University has had to remain unrecorded. If there be grave omissions or misplaced emphasis, I will hope with Pliny the Younger that "history however it is written will always please".

LONG ASHTON RESEARCH STATION

JUBILEE CELEBRATIONS*

LONG ASHTON, the second oldest agricultural research station in Britain, began in 1903 as a private foundation—the National Fruit and Cider Institute. The Institute evolved from the pioneer experiments in cider-making carried on at Butleigh Court, Somerset, by Mr. Robert Neville Grenville. His enthusiasm stimulated the Bath and West and Southern Counties Society, in collaboration with the County Councils of Devon, Gloucester, Hereford, Somerset and Monmouth, to establish at Long Ashton an Institute for research and instruction in cider-making and fruit-growing. Thanks mainly to Mr. A. E. Brooke-Hunt, superintending inspector of the Board of Agriculture, the Institute, from its inception, was aided by a small government grant.

The Institute continued independently, under the management of governors nominated by the contributing bodies, until 1912, when it became formally associated with the University of Bristol as one of the research institutes set up at that time by the Board of Agriculture and the Development Commissioners. Under this scheme, the subjects of research at Long Ashton were widened to include all aspects of fruit culture and the control of pests and diseases of fruit crops, and the enlarged Institute was given the name of the Long Ashton Research Station. Its administration became the responsibility of the Agricultural Committee of the University, on which the National Fruit and Cider Institute was given agreed representation. This Committee now includes representatives of the following bodies: Council and Senate of the University, the Governors of the National Fruit and Cider Institute, the Ministry of Agriculture, the contributing counties, and the national associations concerned with the manufacture of cider and fruit juices. Since 1931 the Station has been one of the national research institutes the work of which is co-ordinated by the Agricultural Research Council. The Station's income is now largely derived from grants made to the University by the Ministry of Agriculture and the Agricultural Research Council. The scientific staff at Long Ashton numbers thirty-eight, with forty assistant-scientific and office staff; the Station property covers more than 250 acres.

Research at Long Ashton on cider-making and cider orcharding, started in 1903, has received world-wide recognition and maintains its prominence in the Station's programme. The extension of this work since 1931 to include non-alcoholic fruit juices and syrups has provided the basis for a flourishing new British industry. In fruit culture, the work in growth-regulating substances has been specially noteworthy. Fruit-breeding investigations have produced pear, plum and black-currant varieties of high merit. In pest and disease control the special attention given to spray methods and machinery has made Long Ashton a centre for consultation on spraying problems arising both at home and overseas.

The Station has maintained research and advisory work in willow-growing since 1922 and in domestic food preservation since 1930. The work of this Section has recently been extended to include the preservation of meat and poultry, in addition to that of fruit and vegetables.

The plant-nutrition work at Long Ashton enjoys a world-wide reputation. The discovery in 1924 that a major cause of fruit-tree failures was potash deficiency revolutionized fruit production in England. Since 1939 studies of the nutrition of farm and market-garden crops have been included in this work, and, arising from these, the visual symptoms of mineral deficiencies and excesses on a wide range of crop plants have been defined and published in a colour atlas. In 1952 the group of research workers engaged in these investigations was constituted a special Agricultural Research Council Unit for the study of problems of plant nutrition, with particular reference to the micronutrient elements.

The celebrations of the Station's Jubilee, which were jointly planned by the University of Bristol and the National Fruit and Cider Institute, took place during July 22–23. On July 22, the Jubilee Lecture, entitled "Agricultural Research, 1953", at which the vice-chancellor of the University, Sir Philip Morris, presided, was given in the reception room of the University by Lord Rothschild, chairman of the Agricultural Research Council. In a survey of problems of the organization of agricultural research in Britain, Lord Rothschild pleaded for closer contact between the agricultural research institutes and the industries they serve. Without prejudice to the policy of recruiting outstanding scientists and leaving them to develop their own approach to the long-range problems of agriculture, he advocated the listing of the short-term problems in order of economic importance, with the aim of allotting agricultural research facilities in accordance with national needs. He suggested that a reduction in the number of committees dealing with research and administration would be advantageous.

---

* See also p. 264 of this issue.

As examples of achievements of agricultural research in Britain, Lord Rothschild cited the work of the National Institute for Research in Dairying on bacteriophage control in cheese, the success of the Moredun Institute in developing treatments for diseases of farm stock, and the combined operations by Rothamsted, Aberystwyth, the Grassland Research Institute, Jealott's Hill and the Hannah Research Institute in pasture improvement, grass conservation and grass utilization. In referring to the phenoxyacetic acid weed-killers, he gave the estimate that they have, in ten years, already increased British cereal yields by 5 per cent. Dealing with the biological importance of trace elements, he stressed the increases in yield made possible by Prof. T. Wallace's work at Long Ashton. In conclusion, Lord Rothschild described the Long Ashton staff as a happy and productive family.

At a commemorative dinner given by the University in the Great Hall on July 22, the principal speakers were Sir Robert Sinclair (pro-chancellor), Sir Reginald Verdon Smith (chairman of Council), Sir Philip Morris (vice-chancellor), Sir William Slater (secretary of the Agricultural Research Council), Earl Waldegrave (trustee of the Bath and West Society) and the Lord Mayor of Bristol.

The celebrations were continued at the Long Ashton Research Station on July 23, when approximately nine hundred guests of the National Fruit and Cider Institute attended, under the presidency of Captain D. M. Wills, chairman of the National Fruit and Cider Institute and of the Agricultural Committee of the University. After a morning programme including exhibits, demonstrations and plantation tours illustrating the history and present-day activities of the Station, two ceremonies recalled the events of 1903. Near the cider orchard that had been set out under his direction fifty years ago, Prof. B. T. P. Barker, emeritus professor of agricultural biology in the University of Bristol, completed the planting of a tree of Ashton Brown Jersey, a variety that had been found on the Station farm in 1903. In the Station Library, Lord Bledisloe, senior vice-president of the Bath and West Society, unveiled a plaque presented by the Society to commemorate its part in the founding of the Institute and recording the close collaboration between the Society and the Station throughout the fifty-year period.

These ceremonies were followed by addresses by the Right Hon. Sir Thomas Dugdale, Minister of Agriculture, Mr. C. P. Norbury, vice-chairman of the National Fruit and Cider Institute, and Prof. T. Wallace, director of the Station.

Sir Thomas Dugdale cited Long Ashton as an excellent example of the way in which the British agricultural research service has arisen and developed to meet specific needs and problems: the service was not a set plan imposed from above. The success and strength of the Station are the result of the co-operation of all the parties concerned. The Minister emphasized the Government interest in horticulture no less than in agriculture and referred to the friendly relations between Long Ashton and the National Agricultural Advisory Service. He paid tribute to the founders of the Station and to its directors, Profs. Barker and Wallace. He announced that Prof. Wallace, who has given much help to the Agricultural Improvement Council, has now accepted his invitation to become a member of that body.

Finally, the Minister referred to the future policy and needs of the Station. While disclaiming the role of a *deus ex machina* (the Minister had arrived in a nearby field by helicopter) he said that he hoped that Long Ashton will see work in hand next year on its much-needed new glasshouses.

Mr. Christopher Norbury, a leader of the British fruit-growing industry, described Long Ashton as one of the foundation stones on which the industry was built. Its work has made possible increased production per acre and per man, through greater regularity of cropping, the better control of pests and diseases and the solution of problems of fruit tree nutrition. Long Ashton also studies fruit products that are providing new outlets for apples and black currants.

Mr. Norbury paid tribute to the University of Bristol for its part in developing not only Long Ashton but also the Chipping Campden Research Station, the work of which on canning has been so valuable to fruit growers. He welcomed the increased Government support for the agricultural research and advisory services, both of which are of vital importance to our survival as a nation.

Prof. T. Wallace thanked, in particular, the Minister for his presence and gracious speech and the Bath and West Society for the presentation of the plaque, referring specially to two distinguished representatives of the Society—Lord Bledisloe and Sir Charles Miles. He welcomed also Sir John and Lady Russell, Sir Donald and Lady Vandepeer, Sir Alan Hitchman, Sir James Scott Watson, Sir Reginald Franklin, Sir William Slater, Dr. T. Loveday and Dr. H. V. Taylor. Among the representatives of organizations concerned with agriculture and horticulture, Prof. Wallace greeted delegates from the Royal Agricultural Society, the Central Horticultural Committee of the National Farmers' Union, the Royal Horticultural Society and the Farmers' Club.

Commonwealth and other Governments whose representatives were welcomed by the Director included Canada, New Zealand, Australia, South Africa, Pakistan and the Netherlands. Prof. Wallace expressed his appreciation to the growers, cider-makers and business firms for their past help and their support of the Jubilee celebrations.

The research stations (East Malling, John Innes, Rothamsted and others), universities and agricultural colleges were warmly thanked for their participation, and Prof. Wallace made a special reference to the presence of Prof. Barker, who was also celebrating his jubilee of service at the Station.

In conclusion he quoted a slightly modified version of a sentence written by Mr. Brooke-Hunt in 1903 describing the establishment of the National Fruit and Cider Institute: "It began, as most things do that really last, in only a small way, and it has developed naturally in accordance with the needs of the times; its spirit remains young and the potentialities are great; and it is hoped that its career may continue to be one of increasing usefulness, not only to this generation, but to others which are to follow".

R. W. MARSH

THE DEEP SCATTERING LAYER IN THE SEA: ASSOCIATION WITH DENSITY LAYERING

By Dr H. F. P. HERDMAN
National Institute of Oceanography

THE work planned for the sixth commission of the R.R.S. *Discovery II* during 1950–51 included an extensive echo-sounding programme and, when conditions were suitable, efforts were made to record the phenomenon now generally known as the 'deep scattering layer'. Unfortunately, since a large part of the commission was spent in the Southern Ocean in winter, the sea and wind were often a severe hindrance to echo-sounding when the ship was under way. Nevertheless, it was possible on a number of occasions—even in winter—to record the deep scattering layer in the form hitherto noted by American and French observers[1,2].

Our observations ranged from the Western North Atlantic to the Antarctic, but were mostly made in the Pacific and Indian sectors of the Southern Ocean. In general, the scattering layer echo traces were similar in character to those previously described by most authorities, and the vertical migration of the layer, to which a biological significance has been attached, was noted on several occasions, especially between lat. 30° and 45° S. There were also nights when the layer remained at constant depths ranging from 60 to 110 fathoms (110–201 metres); such constant-depth echoes, however, were noted only in high latitudes, near the ice edge, and in winter.

The depths at which the deep scattering layer was found were nearly always less than those generally recorded, both in the Southern Ocean and in warmer seas. Most of the layers recorded by the *Discovery II* ranged in depth between 90 and 120 fathoms (165 and 219 metres), with only an occasional observation of a recognizable layer at a depth of 180 fathoms (329 metres). The thickness of the layer varied between 20 and 75 fathoms (37 and 137 metres). In connexion with the figures quoted above, it should, however, be noted that the frequency of the Kelvin and Hughes Type *MS. 21 E* deep-water echo sounder used in the *Discovery II* was only 10 kc./s., as opposed to frequencies of 18–24 kc./s. normal in American echo-sounding instruments, and with which it would seem that most previous examples of the oceanic deep scattering layer have been recorded. This difference in frequency, with its consequent difference in wave-length of the sound transmitted, may (when the scattering can be attributed to a concentration of marine animals) cause echoes to be received from a different group of animals at another level. Recent work by Hersey, Johnson and Davis[3] tends to confirm this hypothesis.

On certain occasions the sounding records (see Figs. 1 and 2) showed echo markings, at depths near the surface, which appear to differ significantly from most of the previous recordings, being thinner and more sharply defined. They agree closely, however, with recordings made by the R.V. *Ernest Holt* in the Barents Sea in 1951[4].

This type of scattering layer was first noticed during a zig-zag cruise along the Pacific ice edge, made by the *Discovery II* in late November 1950. At a number of stations worked in or near the edge of the pack ice, the echo sounder was run while the ship was stopped, or making only 2–3 knots, and in several instances a recording of a scattering layer or layers was obtained. Fig. 1 shows a section of the echo sounding record taken at one of the stations in this series (No. 2759, in lat 62° 12′ S., long. 172° 12′ W.), when the ship was towing nets in a fairly open lead inside the edge of the pack ice. A preliminary analysis of the plankton samples obtained here does not reveal any particular concentration of animals. The catches were, in other words, normal for the region of the ice edge.

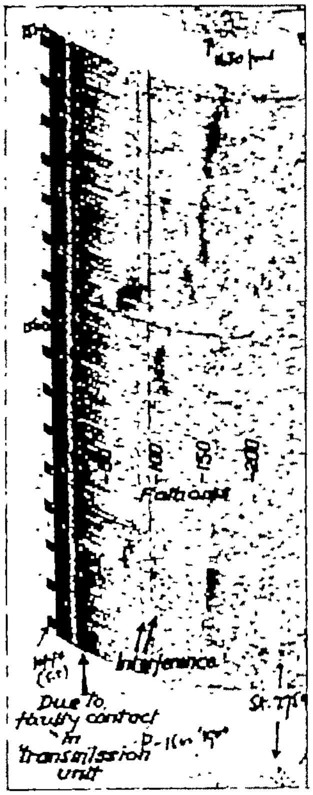

Fig. 1

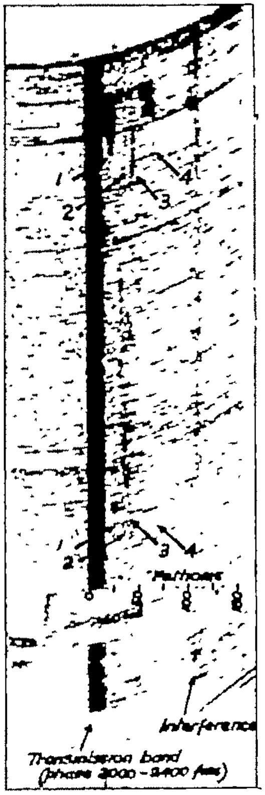

Fig. 2

Fig. 1. Echo record, station 2759 (lat. 62° 12′ S., long. 172° 12′ W.). In lead in pack ice. Soundings, at beginning of record 1,725 fm., at end 1,650 fm. (both depths uncorrected)

Fig. 2. Echo record, station 2775 (lat. 56° 00′ S., long. 153° 35′ E.) Sounding, 1,960 fm. (uncorrected). Multiple echoes recorded during use of bathythermograph marked 1–4 (see also Fig. 3)

Slightly more than three weeks later, in mid-December, observations were being made on the Antarctic Convergence, not far from Macquarie Island. Here, the Antarctic Convergence is, in most seasons, much more sharply defined than in other sectors of the Southern Ocean. The Antarctic Convergence is a continuous natural boundary around Antarctica where the northward-flowing cold Antarctic surface water sinks below the warmer and less-dense sub-Antarctic water, and it can usually be detected by an abrupt change in surface temperature. Below the surface there is an equally detectable boundary between the sinking cold water and the warmer water of the sub-Antarctic region.

At one station in this region (No. 2775, in lat. 56° 00′ S., long. 153° 35′ E.) the echo sounder gave the record shown in Fig. 2. At the time, it was assumed that the multiple echoes represented reflexions from a very diverse scattering layer; but

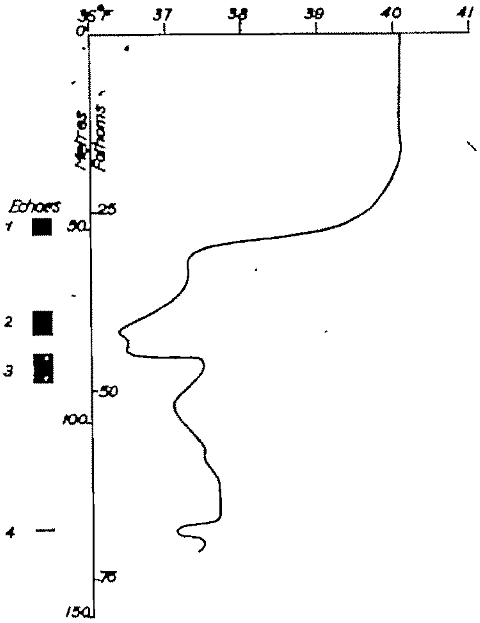

Fig. 3. Temperature, St. 2775, from bathythermograph record. Range of multiple echo layers (1–4), recorded at the same time, shown on left of depth scale

later, when the isotherms comprising the observations taken on this crossing of the Antarctic Convergence were being plotted, it appeared that there might be some correlation between the depths of the multiple echoes and the temperature layering as shown by the bathythermograph. Reference to Fig. 3, where the temperature record has been plotted against depth, and the depth of the various echo layers noted against the latter scale, shows that there appears to be a certain measure of agreement between the depths at which temperature discontinuities occur and those of the various echoes recorded.

A check was then made on the recordings of the scattering layer taken near, or on, the ice edge during the previous month, and at three stations there appeared to be some measure of correlation between temperature discontinuities as recorded by the bathythermograph and scattering layer recordings such as those shown in Fig. 1 (an ice-edge station). The agreement, though not quite so good as that noted on Station 2775, was sufficient to give a clear indication that the presence of the sound scatterers, whether biological or not, can be closely associated with the temperature and density layering. Echo traces almost identical in character to those shown in Fig. 2 have been obtained from a convergence area by the R.V. *Ernest Holt* at several places in the Arctic Ocean where the relatively warm Atlantic water meets cold Arctic water and gives rise to a marked but complicated layering of the water[4]. The correlation of temperature layering, as recorded by the bathythermograph, with the multiple traces on the echo-sounder record, is remarkably good.

Burd and Lee remarked in 1951[5], in summarizing the observations on the deep scattering layer, that no generalizations as to the cause were possible; but the observations since made by the *Discovery II* and the *Ernest Holt* have revealed not only layers which, by their diurnal vertical movement, can be argued to be biological in origin, but also others which are associated with discontinuity in the temperature or density layering. On the other hand, Tchernia[2] has recently stated that no physical discontinuity known at present in oceanographical circles can be invoked to explain the deep scattering layer. The recordings made by the *Discovery II* and the *Ernest Holt* as widely apart as the Arctic and Antarctic seas would, however, seem to show that there can be some connexion between the origin of at least one form of the deep scattering layer and physical discontinuities. Whether this connexion depends entirely on the purely physical boundaries, or on possible concentrations of falling detritus or animal life, checked in their fall by a sudden change in density, is at the moment a matter for conjecture.

OBITUARIES

Prof. J. B. Dale

John Borthwick Dale, formerly assistant professor of mathematics at King's College, London, died on July 1, aged eighty-two. He was born on June 3, 1871, the eldest son of James F. Dale, a cabinet maker in Great George Street, Liverpool. He had a brilliant career at the High School of the Liverpool Institute (1880–90), and was elected in December 1889 to a foundation scholarship at St. John's College, Cambridge. He won prizes there, including the Wright's Prize and the Sir John Herschel Prize for astronomy in 1892; he was sixth Wrangler in the Mathematical Tripos of 1893, and obtained a first class (Div. 3) in Part II in 1894.

In 1894 Dale was brought on to the mathematical staff at King's College, London, by Prof. W. H. H. Hudson as a temporary assistant lecturer to fill an unexpected vacancy.

A year later he was joined by R. W. K. Edwards, father of the present rector of Aberdeen University, and these two, with Hudson, constituted the entire staff of their department at that time. In 1898 their salaries were raised from £120 to £150 a year, and in October 1902 they were each given the title of lecturer. When, in December 1903, S. A. F. White (see *Nature*, 167, 259; 1951) was elected to the chair of mathematics, Dale was given the rank of assistant professor, which he held until his retirement in 1936. He married in 1902 Agnes Smith Taunt, of Chelsea, who died in 1924, and in 1931 Mary Lindsay Gladstone, of Rock Ferry, Cheshire, who survives him.

Dale was known chiefly for his "Five-Figure Tables of Mathematical Functions", which were first published by Edward Arnold in 1903 and ran to several editions, the last appearing in 1949. They held a unique position at the time of their appearance and for many years afterwards.

He also compiled "Logarithmic and Trigonometric Tables to Five Places of Decimals", published by Arnold's in 1905 and running to twelve impressions before a new edition came out in 1947. He collaborated with Prof. G. M. Minchin in producing "Mathematical Drawing", issued by the same publishers in 1906. He had some ten papers to his credit, chiefly in *Nature*, *Astr. Nach.* and *Mon. Not.*

Roy. Astro. Soc., his interest being mainly in astronomy, though he published a paper on "The Dissipation of Energy by Electric Currents" (*Proc. Roy. Soc.*, 70). A treatise on differential equations, in preparation in 1912, was never finished.

Many generations of students still recall Dale as a first-rate teacher. Problems were solved with a satisfying completeness; no untidy ends were ever left in a lecture; and his sentences were delivered in a sonorous voice, as of one speaking *ex cathedra*. Not even the second-year engineers, to whom he lectured regularly, could throw him off his balance. Once, when lecturing on hydromechanics, he said, "We now proceed to consider pitching and rolling". From a back bench came an agonized cry of "Steward !" "We are not concerned with the internal stresses and strains of the passengers", said Dale in his even voice, and went straight on with the lecture. He was always human and practical, and ready to adapt the presentation of his subject to the class before him.

After retirement Dale went to live near Chalfont St. Giles, where he remained until his death. The War made country life much more strenuous than it had been, but until he had a major operation in the winter of 1949–50 he scarcely knew what illness was. Even after this, he recovered a good deal of his strength until his last illness overtook him a few weeks before his death.

J. T. Combridge

W. R. B. Battle

Walter Ravenhill Brown Battle was drowned on July 13, in a glacier stream on Baffin Island.

"Ben" Battle, as he was known to his many friends, was born in Leeds on December 23, 1919. He was educated there and took a degree in geography at the University of Leeds. He became a keen traveller and mountaineer, and in 1948 organized and led a four-man expedition to East Greenland, where he made geomorphological and glaciological investigations on Pasterzebreen. Battle returned to the same area in 1949 and afterwards went to Cambridge as a research student to investigate the action of frost and water in the formation of cirques. During this period he twice visited Jotunheimen in Norway with parties from Cambridge. Towards the end of 1952 he went to McGill University and continued his studies as Senior Carnegie Fellow of the Arctic Institute of North America. At the time of his death he was working on Penny Highland, Cumberland Peninsula, with a party from the Arctic Institute.

J. D. M. Blyth

NEWS and VIEWS

Radar Research Establishment, Malvern

As announced by the Minister of Supply in the House of Commons on July 28, the two establishments engaged in radar research in Malvern—the Telecommunications Research Establishment (T.R.E.) and the Radar Research and Development Establishment (R.R.D.E.)—are to be amalgamated, and the new organization will be known as the Radar Research Establishment. The Telecommunications Research Establishment grew out of the Bawdsey Research Station, which was set up in the years just preceding the Second World War specifically for research on radar, a subject of which the existence and possibilities were at that time known only to very few. During the War the Establishment was responsible for the creation of the many radar devices used by the Royal Air Force and, in particular, for the development of microwaves. During the years after the War these new techniques were applied to peacetime problems, including civil aviation and more recently to the new problems of defence, notably the development of guided weapons. In addition, however, a strong physics research group has been built up which has carried out research on a variety of subjects, including the extension of the microwave spectrum to still shorter waves, low-temperature physics, semi-conductors and infra-red spectroscopy as well as advanced electronic techniques; much of this work has been published in the scientific journals. The Radar Research and Development Establishment has a much longer history and goes back to a group set up in 1917 to work on searchlights. The new radar techniques were applied during the Second World War to the problems of directing searchlights and more especially to the accurate control of anti-aircraft fire. The Establishment has since then continued to be responsible for the radar needs of the Army, including new developments in guided weapons; some interesting work on galactic and solar radiation at radio wave-lengths has also been carried out. The new Radar Research Establishment will be responsible for research for the Army, Air Force and Fleet Air Arm on defence problems in the fields of radar, guided weapons, etc., and also for fundamental research on new techniques which might lead to a solution of these problems.

Mr. W. J. Richards, C.B.E.

Mr. W. J. Richards has been appointed director of the Radar Research Establishment, Malvern (see above), as from September 1. After graduating in engineering at the University of Manchester, having studied under Prof. A. H. Gibson, in 1925 Mr. Richards joined the Royal Aircraft Establishment, Farnborough, where he carried out research, mainly on aircraft instruments. In 1936 he became head of the Instrument Department, a post which he held until 1942, when he became a deputy director of scientific research in the Ministry of Aircraft Production, London. There his work was mainly concerned with aircraft armaments, but in the period immediately after the Second World War he was one of the pioneers in the field of guided weapons and took part in the first British mission on this subject to the United States. In October 1946 Mr. Richards was appointed to his present post as chief superintendent of the Telecommunications Research Establishment.

I.C.I. Dyestuffs Division: Mr. G. S. J. White

Mr. G. S. J. White, chief colourist of the Dyestuffs Division of Imperial Chemical Industries, Ltd., has been appointed division director in charge of Technical Service Departments in succession to Dr. F. J. Siddle, who has taken up the post of managing director of the 'Terylene' Council. It is twenty-four years since Mr. White joined Dyestuffs Division's headquarters at Blackley, Manchester. He is a Londoner by birth, and went from the University of

Oxford to the Leather Section of the Dyehouse Department, where he worked for nine years before he took charge of the Application Research Section. In 1942 he was promoted to the position of assistant chief colourist and two years later became head of the Dyehouse Department. During the course of his career, he has travelled widely in India, South America, the United States, Canada, New Zealand, Australia and most of the European countries. Away from business his principal activities are connected with the Society of Dyers and Colourists, of which he is a member of the Council and chairman of the Lancashire Section, and with the Textile Institute, of which he is a Fellow. He has also concerned himself in the affairs of the Manchester College of Technology and recently completed his third year as external examiner in the Textile Chemistry Department.

Agriculture at Leeds: Prof. N. M. Comber

PROF. N. M. COMBER, who has been associated with the University of Leeds for more than forty years, retires at the end of the present session with a distinguished record in the service of agricultural science and education. A graduate of the University of London (Royal College of Science), he went to the Department of Agriculture as assistant lecturer in agricultural chemistry in 1913. In 1925 he became professor of agricultural chemistry, and seven years later head of the Department. His work has been notable for important contributions to soil chemistry and his authorship of books on the subject as well as his active interest in and devotion to agricultural education. He has served on the Council of the Royal Institute of Chemistry and the Society of Chemical Industry, and he has been chairman and treasurer of the Agricultural Education Association. Further, he has been chairman of the Yorkshire Branch of the Rural Community Council and done much by his support and encouragement for the young farmers' club movement in Yorkshire. In 1949 he was elected president of Section M (Agriculture) of the British Association; but his address, entitled 'Farming Science and Education", was read for him as illness prevented his attendance. He has served on many university committees and on the Agricultural Sub-Committee of the University Grants Committee, and the value of his knowledge and experience will be greatly missed.

Prof. T. L. Bywater

PROF. T. L. BYWATER, at present occupying the Strathcona–Fordyce chair of agriculture at the University of Aberdeen, succeeds Prof. Comber as head of the Department, and will be professor of agriculture. He is no stranger to Leeds, as after graduating with first-class honours in agriculture at the University College of North Wales in 1927 and gaining the M.Sc. at Wisconsin University in 1928, he was appointed to the Department of Agriculture as assistant lecturer in agriculture. He became lecturer in 1934, senior lecturer in 1945, and left in 1946 when he accepted the chair at Aberdeen. During the War he was seconded for advisory work to the West Riding Agricultural Executive Committee. He specializes in animal husbandry and has carried out investigations in fat lamb production, pig rearing, sheep crossing and bullock fattening. He will be able to make full use of the new University farm in continuing this work.

The Agricultural Improvement Council

THE Agricultural Improvement Council, set up by the Ministry of Agriculture and Fisheries in 1941, has now been reconstituted, having reached the end of a further three-year period of office. A major function of the Council is to keep under review the technical problems affecting the agricultural (including horticultural) industry and to advise the Minister on the need or otherwise for research and investigation for their solution. The newly constituted Council has now a somewhat wider responsibility, and it includes in its orbit the study of estate management problems covering both farm buildings and other forms of fixed equipment. Before work on a problem can be undertaken it must be clearly defined and its importance assessed; this the Council achieves through one or other of its several committees. It is also an equally important function of the Council to ensure that the agricultural community shall be acquainted as rapidly as possible with the results of research after they have been tested on a scale large enough to warrant their introduction to the practising farmer.

The work of the Council is aligned on one hand with that of the Agricultural Research Council, to the notice of which it brings matters requiring research attention, and on the other with that of the Agricultural Advisory Services, to which it looks for answers to those other problems that can best be solved on commercial farms and experimental stations and through which it puts over the results of research to the farmer.

The membership of the Council, which includes farmers, land-owners, men of science and others, is as follows: Sir Alan Hitchman (*chairman*), Sir Edward Salisbury (*vice-chairman*), Prof. F. Blakemore, Harold Collison, Sir Frank Engledow, H. R. Finn, Frank Griffith, T. Neame, the Duke of Northumberland, H. J. Rathbone, F. Rayns, Prof. Ellis J. Roberts, Prof. H. G. Sanders, F. A. Secrett, Sir William Slater, H. Cole Tinsley, Sir James Turner, Prof. T. Wallace and W. Morley Davies (*secretary*).

The Commonwealth Bureau of Pastures and Field Crops

THE Commonwealth Bureau of Pastures and Field Crops, which has been attached to the Welsh Plant Breeding Station, Aberystwyth, for the past twenty-four years, will be transferred to Hurley, Berkshire, in August 1953, where it will be attached to the Grassland Research Station, of which Dr. W. Davies is director. This Bureau, one of the ten Commonwealth agricultural bureaux, was founded at Aberystwyth in 1929, its first consultant director being Prof. (now Sir) George Stapledon. For the first twenty years of its existence the Bureau was in charge of Dr. R. O. Whyte, who was succeeded as director in 1949 by Mr. A. G. G. Hill, formerly director of the East African Agricultural Research Institute, Amani. The Bureau issues the well-known quarterly abstract journals *Herbage Abstracts* and *Field Crop Abstracts*, in addition to its other activities.

Medical Research Council: Applied Psychology Research Unit

DR. N. H. MACKWORTH has been appointed director of the Medical Research Council's Applied Psychology Research Unit, at Cambridge, as from October 1. He succeeds Sir Frederic Bartlett, who directed the Unit in an honorary capacity while holding the chair of experimental psychology in the University. Dr. Mackworth, a whole-time member of the Council's staff, was formerly assistant director. Under arrangements recently agreed between the University and the Council, the larger part of the Unit's work will in future be done outside the University Department of Experimental Psychology, in accommodation acquired by the Council at 15 Chaucer Road, Cambridge, which will be the official address of the Unit from October 1953; but the association with the Department will be preserved, and some members of the Unit will continue to be accommodated in it. A few former members of the Unit have been detached and will in future work wholly in the Department under the general direction of Prof. O. L. Zangwill, who has succeeded Sir Frederic Bartlett as professor and head of the Department.

British Caribbean Meteorological Service

The director of the British Caribbean Meteorological Service, the most recently formed weather service within the British Commonwealth, has recently published his first annual report (British Caribbean Meteorological Service. First Annual Report 1952. Pp. 23. (Trinidad: Government Printing Office, 1953.) 24 cents). The service was formed in accordance with recommendations made by a conference representing the local Colonial Governments and H.M. Government in Great Britain which met in January 1951. The director, Mr. W. A. Grinsted, formerly of East Africa, set up his headquarters in Trinidad in November 1951 (see *Nature*, 168, 769; 1951). The service has three main meteorological offices providing weather forecasts for a large area and long-distance aviation route forecasts at Piarco (Trinidad), Palisadoes (Jamaica) and Nassau (Bahamas). The provision of hurricane warnings is a very important part of their work during the hurricane season. These offices were previously in the charge of the British Meteorological Office, many of whose staff are still serving in them on loan to the new organization. Reporting stations are maintained in many of the islands and continental territories from the Bahamas to British Guiana and Barbados to British Honduras. Climatological records are collected at the Headquarters and many inquiries have been answered from them. Our best wishes are extended to the new organization with its heavy responsibilities for the meteorological service of this great area.

Characteristics of Current Types of Photomultipliers

As a detector of light signals the normal photo-cell and valve amplifier is limited by the inherent thermal noise of the coupling resistance and the shot effect of the first valve, so that in the fields of spectroscopy, astronomy and nuclear physics, where a highly sensitive light detector is required, the photomultiplier has recently gained popularity. The survey of current types of photomultipliers which is given in the article by Dr. W. E. Turk, of E.M.I. Research Laboratories, Ltd., Hayes, Middlesex (Photoelectric Spectrometry Group Bulletin, No. 5; pp. 100; October 1952) is therefore very useful. First a brief description is given of the phenomenon of secondary emission and of the basic and early designs of photomultipliers. The characteristics of an ideal tube—for example, a highly photosensitive cathode, wide spectral response, high gain in the multiplier section and a high signal/noise ratio—are then outlined, together with the various corresponding practical requirements. Next, the different commercially available tubes are examined and compared with one another and with the ideal tube. A table, in which is collected the essential data of five Cintel, eight EMI, three Mazda and seven RCA types of photomultipliers, is given, and this should be a valuable and easy guide to the selection of the most appropriate tube for a particular purpose. Finally, some very useful practical comments are made about the various techniques employed to improve the signal/noise ratio, the variation in the dark-current of photomultipliers after storage in the dark, and power supplies for photomultipliers.

Petroleum Consumption in Great Britain during 1951–52

The Petroleum Information Bureau (29 New Bond Street, London, W.1) has issued a booklet on "Statistics Relating to Consumption and Refinery Production 1951 and 1952" which reveals that the consumption of petroleum products in the United Kingdom still shows an upward trend. The total for all products for 1951 was 16,887,908 tons, and for 1952 17,520,145 tons. Of these, the delivery of motor spirit, industrial spirits (including benzole), white spirit and kerosene, accounted for 1,435,811 tons in 1951 and 1,443,173 tons in 1952. Heavy fuel oils (including refinery consumption) consumed by the inland trade were 6,001,013 and 6,354,269 tons, respectively. Other products include lubricating oils and greases, paraffin wax and scale, propane and butane, bitumen, etc. Indigenous materials made available for distribution (excluding shale and crude oils) amounted during the respective years to 111,862 and 108,899 tons of motor and aviation spirit (by hydrogenation) and 78,996 and 175,493 tons of refined benzole. It is noted that no distribution of motor spirit by low-temperature carbonization was made in the two-year period covered by this statistical analysis.

Spectrophotometric Study of the Shell Star ζ Tauri

A spectrophotometric comparison of the shell spectrum of ζ Tauri has been made by Anne B. Underhill, of the Dominion Astrophysical Observatory, Victoria, B.C., from high-dispersion plates in 1948 and 1950, and details of the study have been published by the Observatory (Pub. Dom. Astrophys. Obs., 9, No. 2; 1952. Ottawa: Queen's Printer; 25 cents). It is known from the previous work of Adams, Miss Losh, and Struve and Hynek, that this star shows radial velocity changes which suggest binary motion with a period of 132·91 days, and that secondary irregularities of a variable nature, apparently connected with the shell, are superposed on this motion. After Slettebak had announced in December 1949 that the shell spectrum of the star was unusually strong, many more lines being visible than in 1940 and 1941, it was decided to use moderate- and high-dispersion plates to investigate the change and also to determine the physical properties of the shell, by a comparison of the previous plates of 1938 with those of 1950. In the spectrum of the underlying star were lines of NII, OII, SiIII, AlIII and also HeI and H, for which reason the star has been classified as *B2* or earlier, not *B3* as given by previous authors. The periphery of the underlying star was found to be rotating with a speed of about 350 km./sec. A list of the shell lines between λ 3896 and λ 4923 is given in the paper, and it is shown that the mean degree of ionization in the shell was less in 1950 than in 1938. The apparent rotational velocity of the shell is 150 km./sec., and, on the assumption of the conservation of angular momentum between the shell and the star, this gives a projected velocity of rotation of the shell of 230 km./sec. The fraction of neutral, once-ionized and twice-ionized iron for a number of temperatures and electron pressures computed by Saha's equation are given, and from a consideration of the data it is shown that in 1938 the shell may be described as a body of gas in thermodynamic equilibrium with $T \sim 9{,}000°$ K. and log $P_e \sim 1·5$, while in 1950 log $P_e \sim 3$, the temperature remaining practically the same. It was pointed out by Struve in 1938 that this description cannot account for the appearance of HeI λ 3965 in the shell spectrum, which requires that the radiation field be dilute and of a high temperature, but it is shown that these apparently contradictory requirements are reconciled and that the shell is probably confined to an equatorial ring or bulge. The 1949–50 radial-velocity measures of the star and shell show that the star was expanding with respect to the shell for a short time after Slettebak had announced an enhanced shell spectrum in *H.A.C.* 1050. It is suggested that the increase of pressure—probably the cause of the change of ionization observed—was due to the outer layers of the underlying star expanding for a short period and compressing the equatorial bulge.

The Comet of November 1948

A REPRINT from *Science and Culture* (**14**, p. 302) has been circulated by the director of the Solar Physics Observatory, Kodaikanal, and this publication contains a description of the comet of November 1948, with nine photographs taken between November 11 and December 7, 1948. Visual and photographic observations of the comet were made on thirteen days, and on two other days only visual observations were possible. A table lists its spherical co-ordinates between the above dates, and various other details are given with three diagrams. The comet, known as 1948 *l*, made a spectacular appearance during the total eclipse of the sun on November 1, 1948; its perihelion distance was 0·135335 and its orbit was practically parabolic.

Love Waves in Earthquakes

IN the seventh paper of his recent series on surface waves, Yasuo Satô has examined theoretically the travel-time of Love waves (*Bull. Earthquake Res. Inst., Tokyo Univ.*, 30, Pt. 4, 305; December 1952). The work includes calculations, (1) assuming the focus is in the superficial layer, and (2) assuming the focus is in the lower medium. He obtains equations for (1): $x_s' = (H + E)/[(V_{\text{Love}}/V_s)^2 - 1]^{1/2}$, x_s' being the critical distance where Love waves can first be observed, H the depth of superficial layer, E the depth of the point below the bottom of the superficial layer where the emergent ray—produced backwards—would intersect the vertical through the focus, and V_{Love} and V_s the velocities of the Love and transverse waves respectively in the superficial layer. For (2), $x_0 = H/[(V_{\text{Love}}/V_s)^2 - 1]^{1/2}$. Assuming a structure for the upper crust in Japan as determined by T. Matuzawa, the following two sets are obtained: $\rho' = 3·4$ gm./cm.^{3}, $\mu' = 68·9$ km. gm. sec., $V_s' = 4·5$ km./sec.; $\rho = 2·7$ gm./cm.^{3}, $\mu = 29·4$ km. gm. sec., $V_s = 3·3$ km./sec. Satô calculates that the intercept time of a wave with a period of half a minute is about ten seconds, and the critical appearance-distance is about two hundred kilometres. This theoretical result agrees with some unpublished observational facts ascertained by T. Akima using his low-pass filter.

Pythium Parasites of Sitka Spruce Seedlings

FUNGI belonging to the genus *Pythium* are frequently found on the roots of various plants, in circumstances which indicate some degree of parasitism. J. H. Warcup (*Trans. Brit. Mycol. Soc.*, **35**, Part 4, 248; December 1952) has demonstrated that three species were actively parasitic on Sitka spruce seedlings grown on alkaline soil. One species (*P. ultimum*) was indeed found to be naturally abundant in the soil of nurseries in alkaline regions (pH 6·8–7·2) and rare or absent in those under more acid conditions (pH 5·3–5·5). Symptoms varied from 'damping-off' to a slow foot-rot. Partial sterilization by steam or formalin treatment controlled the disease; the plants, moreover, grew much better after this treatment and were more numerous.

Announcements

MR. H. NORMAN G. ALLEN has been re-elected chairman of Council of the British Internal Combustion Engine Research Association for the current year.

MR. T. O. MUIRHEADHAIGH, of the Department of Industry and Commerce of the Republic of Ireland, has been appointed chairman of the National Committee for Geodesy and Geophysics in succession to Mr. J. C. B. MacCarthy (*Nature* of July 25, p. 142).

WELLCOME Pharmaceutical Research Fellowships, of an annual value of £350 each, have been awarded to J. Thomas and G. L. Willey for a second year in both cases. Mr. Thomas will continue, in the Department of Pharmacy of the University of Manchester, his study of the chemical synthesis of biological activity, particularly bactericidal action, of a new series of quaternary ammonium compounds. At the University of Leeds Mr. Willey will continue his research on the possibility of selectivity of action of nicotine-like stimulant compounds.

THE Pharmaceutical Society has awarded its Ransom Fellowship, worth £300 a year for two years, to Mr. Keith Henry Palmer for research, in the Pharmacy Department of the University of Nottingham, on plant chemistry with special reference to the separation of naturally occurring mixtures of alkaloids. The Society's research scholarship, also of £300 a year for two years, has been awarded to Mr. Kenneth Albert Kerridge, for work in the Department of Pharmacy, Chelsea Polytechnic, on the aspects of trace metal chelation in relation to bacteriostasis.

THE English Electric Research Fellowship in Aeronautics, tenable at the College of Aeronautics, Cranfield, has been awarded for the academic year 1953–54 to R. G. Anderson, of the Mathematical Section of the Aircraft Division of the English Electric Co., Ltd., Warton Aerodrome, Preston. The Perring Scholarship for a two-year course at the College, beginning in October this year, has been awarded to A. Coull, a graduate in civil engineering of the University of Aberdeen.

THE SCIENTIFIC AND TECHNICAL WORKER IN ECONOMIC DEVELOPMENT

ONE of the Committees of the British Commonwealth Scientific Conference, held in Canberra and Melbourne during February–March 1952, considered the great demands now being made by the technical assistance plans of the United Nations, including the Economic and Social Council and the Specialized Agencies as well as the Colombo Plan. The Committee was convinced that the provision of scientific and technical man-power for such purposes must be a continuing responsibility, but thought that more permanent effects would result if the countries concerned sent their own carefully selected nominees to appropriate centres for specialized training. It recognized, however, that where urgent action was necessary the dispatch of specialist workers to the less-developed country might be unavoidable.

The Committee was concerned at the confusion which has resulted from the ever-growing and uncoordinated demands for scientific and technical man-power, a matter which had already attracted the attention of the Parliamentary and Scientific Committee, as well as of Political and Economic Planning. On the Committee's recommendation, the Conference adopted a resolution recommending the Standing Committee to arrange for a study of the problems involved in the supply by the British Commonwealth of scientific and technical personnel to help underdeveloped countries. A main purpose of the Conference was to achieve the maximum of scientific co-operation, though it is of course true that, so far as any adverse effect on the research programme of individual countries is concerned, the heavy demand for technical and scientific assistance to underdeveloped countries can only be mitigated by the adoption of some such measures as have been suggested in P E P Broadsheets (cf. *Nature*, 170, 677; 1952).

Some of the problems involved in this expanded programme for technical assistance were reviewed early this year by Dr. B. J. Bok in an article in *Science* (117, 67; 1953), and the broader aspects of the methods and purposes of planning in the promotion of development have since been discussed in a further P E P Broadsheet (No. 351; February 16, 1953). Dr. Bok's article was concerned rather with what was involved in the way of demands for the services of scientific workers by particular requests for technical assistance. He gave as instances that of the Haitian Government's appeal for help in a programme of fish culture to increase the food resources of that country and a similar development in Thailand; the requirements of the project in fundamental education in Thailand which envisages the planning, organization and operation of the first stage of a ten-year plan of educational improvement; the requirements of some short-term industrial assignments in Jugoslavia; and a malaria eradication project in India.

Apart from these illustrations, Dr. Bok considered the difficult problems involved in the selection of experts to which P E P referred in some detail in its earlier broadsheet. Technical skill and competence alone are often insufficient to make a good expert, and Dr. Bok thinks that the selection of United States experts is particularly difficult, partly because the proper organization for finding the experts is lacking in the United States and partly because the expert is not always assured of prompt employment on his return home from a mission lasting two or three years. Frequently the most desirable experts from a technical point of view lack the essential knowledge of social, cultural and political conditions in other parts of the world, necessitating extensive and expensive briefing. While some experts would be required who have made their career by filling in succession various posts within their fields, in the view of the National Research Council committee which has studied these questions, short-term experts are also required. These latter are usually to be found among scientific workers of considerable repute within their fields who are not always able to be away for extended periods.

The National Research Council committee suggested that, apart from adequate briefing, it is essential to define clearly the assignment of such experts before the departure of the mission and that short-term experts are better used within the framework of an established organization rather than as independent consultants. It is also desirable for all major professional societies to assist in finding the right experts for each assignment by setting up special working committees, as has already been done in the engineering profession. International relations committees of other professional societies have not, so far as Dr. Bok was aware, been active in the recruitment of personnel for overseas services.

With regard to the use to be made of the services of scientific and technical experts, these suggestions run on the lines of the recommendations of Political and Economic Planning. Beyond this, they indicate the need for more support and co-operation from individual scientists and their professional societies. The National Research Council's committee suggested that openings be advertised in professional and technical periodicals, and Dr. Bok remarks that in the United States the National Research Council seems to be the ideal organization to co-ordinate the activities in this field of special committees of the professional societies. The success or failure of recruitment for the technical assistance programme, however, depends ultimately on what individual scientific workers are willing to do in support of that programme, and Dr. Bok's final words here are as true for British as for American scientists.

The latest P E P Broadsheet is concerned less with this individual aspect and responsibility than with the collective aspect and the possibility that experience in one area can give useful guidance for pioneering development in another. Each area has its own particular needs and problems; but P E P's study of international development suggests that it is possible to draw up a set of 'working rules' useful to all who are concerned with development, whether it be re-settlement in Indonesia or the proposed hydro-electric project on the Volta River in the Gold Coast. That in itself is encouraging, and the broadsheet has been issued in the hope of eliciting further suggestions and criticism.

On attitudes and objects of development, the Broadsheet points out that ideas about the nature and purpose of development have changed, and the conception now gaining acceptance includes as an essential feature the improvement of the daily life of the people of the area concerned, whatever the other objects. While development should aim at maximum returns for minimum real cost and with no avoidable destruction of natural resources, increase of physical destruction is not desirable for its own sake but as a means of increasing the well-being of individuals. Long-term development, moreover, is only possible when there is enough determination within the country to push it through and meet and overcome opposition. This can only be secured by leadership within the country to be developed, and while outside agencies or governments will look for this leadership when they are deciding whether to participate in the country's schemes, this factor is one to be weighed by the country's government in selecting from the formidable total of projects that cannot be left to private initiative those to which the resources of the government and also of public authorities can be effectively committed without becoming unwieldy.

The selection of projects, in the view of Political and Economic Planning, has two aspects: choice of projects which make a genuine contribution to well-being, and ultimate selection of those which make the greatest contribution at the least real cost. An adequate survey of the resources, needs and possibilities of an area is an essential safeguard against disappointment and failure ; but, even so, there will often be in practice difficult options between benefits to different groups in a country or between a smaller benefit early as against a greater benefit later. Moreover, the many factors which should be considered as a single pattern in selecting projects should all be kept in mind at every stage of planning. The results of development and its costs must be interpreted widely, and the costs of upheaval set against the benefits of increased consumption or improved health. Alike in the selection and planning of projects and in their execution, the Broadsheet lays much stress on the human aspects of development. The aim should be, if possible, to make the process of development beneficial as well as the end result. Constructive work can be good in itself, and, in stressing the importance of securing co-operation and cultivating mutual respect, P E P is directing attention to the human and social problems of change which are as challenging and important as the technical difficulties and must be tackled with understanding and vision by whatever forms of organization or administration are established to further particular development projects.

SCIENCE IN THE UNITED STATES

THE British Commonwealth Scientific Office (North America), which has been established in Washington, D.C., since the autumn of 1944, is the outcome of the scientific mission under the leadership of Sir Henry Tizard that was sent to Washington in 1940 to facilitate the exchange of scientific and technical information between the Governments of the United Kingdom and the United States. This mission continued throughout the Second World War, being known in turn as the British Technical Mission, the Central Scientific Office, the British Central Scientific Office, and (when, following the successive establishment of separate scientific offices in Washington by New Zealand, Australia and, finally, in September 1944, Canada, the British Commonwealth Scientific Office was established) the United Kingdom Scientific Mission. When the British Commonwealth Scientific Conference met in London in 1946, the value of the Office was already recognized, and the Governments concerned were asked to make suitable arrangements for its continuance as a necessary element in the permanent machinery for scientific liaison. About this time, moreover, the emphasis in the work of the Office was changing from military applications to scientific problems arising from the particular economic and industrial needs experienced by each Mission's own country. The Missions still found, however, that they shared many interests and that the collaboration built up during the War could be profitably continued.

The Office now includes the United Kingdom Scientific Mission and Liaison Offices for Canada, Australia, New Zealand and South Africa. Each Mission is independent and is responsible only to its own Government. They co-operate wherever it is to their mutual advantage, sharing office premises and services, but there is no director: the head of each Mission takes it in turn to act as chairman of a house committee which meets monthly and settles affairs of mutual interest and the operation of common services.

The development of the Office is described in the preface to the "BCSO Review of Science in U.S.A. for the Year ending June 1952", which has recently been published*. Although the first to be published, it is the fifth in a series of such annual reviews and brings together much information of interest to the scientist and technologist in Great Britain which is not always readily available or at best widely scattered. There are references to all the major reports dealing with research and development published in the United States during the year under review so that, as a guide to such source material and the comparison of trends in the United States and the United Kingdom, this review should be sure of a warm welcome, and it is to be hoped that its publication will be continued.

The review begins with a general analysis of the growth and distribution of research and development in the United States. During the past decade this has increased by about 270 per cent and, whereas in 1941 only about 7 per cent of the work in industrial and university laboratories received Federal support, in 1952 this figure is estimated at 39 per cent and the Federal Government now pays for 56 per cent of all United States research and development activities: for 1952–53, this is estimated at 1,640 million dollars out of 2,930 million. Some 91,000 science and technology graduates, more than half of whom are engineers, are employed by the Federal Government, excluding those working on Government projects operated by outside bodies, and, of this total, 58,000 are estimated to be employed on research projects. Altogether some 71,000 professional persons are estimated to be employed in industrial research and development, together with 41,000 technical and 54,000 non-technical assistants.

Expenditure on research and development in the universities rose from 80 million dollars in 1941 to 280 millions in 1952 and is estimated at 350 millions for 1952–53, of which 90 per cent will be for research in the biological and physical sciences, including engineering, and 300 millions of this will come from the Federal Government. This dependence on Federal support as well as the bias towards science and technology is already disturbing educational authorities, who fear that the heavy bias towards applied science will also destroy the balance between applied and pure science in the universities and seriously affect the teaching staff of American universities. Some estimates of the research effort of American universities in terms of man-power are cited for the physical and engineering sciences and for medical research.

---

* British Commonwealth Scientific Office, North America. The BCSO Review of Science in U.S.A. for the Year ending June 1952. Pp. iv+40. (London: H.M.S.O., 1953.) 2s. 6d. net.

The next two sections of the survey summarize the findings of the Paley Commission and other bodies concerned with the conservation of materials, and the position of the National Science Foundation and the work of the Interdepartmental Committee on Scientific Research and Development. There follows a series of brief reports on progress in atomic energy and nuclear physics; building research and techniques; mechanical and production engineering; computing machines; water supply and treatment; chemistry; metallurgy; fuel and power; and the biochemistry of food processing and preservation. Finally, the technical assistance programme of the Mutual Security Agency is described, although with this only the United Kingdom Scientific Mission is concerned. Among new developments referred to in this report are mortars made with polyvinyl acetate emulsions, a new brick, a method by which concrete slabs for upper floors or flat roofs can be cast at ground-level and jacked into position, a novel lathe-cutting tool, a "permionic membrane" for giving potable water from brackish or sea water, a continuous ion-exchange process designed by the Stanford Research Institute, the introduction of butadiene–styrene latex-based paints and the rapidly increasing use of antibiotics in feeding farm animals.

BRITISH COLONIAL WELFARE AND DEVELOPMENT DURING 1952–53

A GLANCE at the "Return of Schemes" made under the Colonial Development and Welfare Acts by the Secretary of State for the Colonies during the period April 1, 1952–March 31, 1953 (Colonial Paper 189. Pp. 26. London: H.M.S.O., June 1953; 1*s*. 3*d*.), reveals the dependence of Colonial research on the funds provided under these Acts and the importance of the legislation contemplated in the 1954–55 session to which the Colonial Secretary, Mr. Oliver Lyttelton, referred in his statement to the House of Commons on June 24. The schemes detailed in the White Paper bring the total commitments for development and welfare schemes under the Acts to £97,662,196, of which £13,889,622 is for the year in question, and for research schemes to £11,710,492, of which £1,087,041 is for the year ended March 31, 1953. Of this, £372,486 is for agriculture, £204,878 for medicine, £204,143 for insecticides, £119,115 for products research (£41,600 of which goes to the Colonial Products Research Council), £47,804 for fisheries, £37,754 for economic research, £31,330 for locust control, £23,293 for tsetse and trypanosomiasis, and £24,088 for social science.

Of the actual research schemes, the largest are £173,380 for the East African Agriculture and Forestry Research Organization, £90,000 for the East African Insecticides Research Unit, £106,597 for the Medical Research Council's Field Research Station at Fajara, Gambia, and £77,515 for the Colonial Microbiological Research Institute at Trinidad. £43,160 goes to rice research in Nigeria, £43,000 to the East African Fisheries Research Organization, £32,935 to the establishment of an Agricultural Research and Experimental Station in Nyasaland, £31,330 to the maintenance of the Anti-Locust Research Centre and its extra-mural work, £29,321 to the East African Institute of Social and Economic Research, £26,450 to the Hot Climate Physiology Unit in Nigeria, £24,000 to malaria research in Trinidad, £19,200 for research into the control of *Stomoxys calcitrans* in Uganda, and £16,900 for fundamental insecticide research at the Silwood Park Station (Imperial College of Science and Technology, London) and at Rothamsted Experimental Station.

Grants of particular scientific interest for development and welfare schemes, apart from those for geodetic, topographical, geological and mineral surveys, include £29,476 for the control of 'sudden death' disease of cloves in Zanzibar, £185,000 for a scholarship scheme for residents in Colonial territories to provide training to qualify for public service, £121,620 to University College, Ibadan, £108,040 for the development of African education, and substantial grants for the improvement or development of roads in Nyasaland (£220,000), Malta (£364,394), North Borneo (£305,900) and British Guiana (£315,416), and for the improvement of water supply or control in British Guiana (£919,481), the Gold Coast (£488,000), Malta (£320,250) and Gambia (£70,000). Of a further £1,230,000 for the Uganda Development Plan, £180,000 is for geology and rural water supplies, £390,000 for education, £120,000 for medical schemes, £150,000 for urban water supplies and £90,000 for agriculture.

UNIVERSITIES' COUNCIL FOR ADULT EDUCATION

REPORT FOR 1951–52

UNLIKE the previous six annual reports of the Universities' Council for Adult Education, the seventh annual report, covering the year 1951–52, attempts to survey the extra-mural work of the constituent universities as a whole*. During the year, the work of University Extra-mural Departments throughout Great Britain further expanded, and the departments in the Council became more closely associated. With the addition of the Universities of Edinburgh, Glasgow and Belfast, the membership of the Council is now twenty-one, and the number of courses and classes conducted was 4,064, as compared with eighteen and 2,067, respectively, during 1945–46. During the 1951–52 session, two committees completed their investigations into the teaching of science and the training of teachers, respectively, while the up-to-date bibliography of adult education and the handlist of current studies in the subject, prepared by the Council's Research and Training Sub-Committee, were published, as a co-operative enterprise, by the National Institute of Adult Education.

* Universities Council for Adult Education. Report on the Year 1951–1952. Pp. 26. (Bristol: W. H. Salt, Hon. Secretary, The University, Bristol, 1953.) n.p.

Apart from its interest in relation to the review of adult education which is now going on, the report records the activities of the last session of the first post-war quinquennium, a period marked by striking advances in extra-mural work; and it appears at a time when further development has received its first check, through economies imposed by the universities themselves. The report is thus of value as a contribution to the stocktaking and reconsideration, in the light of recent experience, of possible lines of development, which are appropriate at the outset of a new quinquennium. The Council suggests that a stage of consolidation has now been reached after the rapid expansion of the post-war years; but it does not expect that consolidation will be possible at the peak of achievement. The warning that checks to the growth of adult education, mechanically applied, may have unforeseen and far-reaching consequences, and that interrupted development cannot be resumed at short notice, is the more impressive for the restraint with which it is expressed.

Nevertheless, the report points out, the universities of Great Britain are entering upon a period of great difficulty with greater strength in resources and reserves than at any previous terms. Apart from the increase in extra-mural staffs, the improvement in their conditions of service, and the greater support of the departments from their universities, grants from the Ministry of Education have increased from £71,000 in 1938–39 to £265,000 in 1951–52, an increase which reflects the encouragement given to adult education through the application of the principles of the Education Act of 1944. Much has also been due to the interest and encouragement of the Ministry of Education and its officers.

The debate on the scope, purpose and organization of liberal adult education continues unabated, and many of the reports on the session's work are marked by critical examination of the function and contribution of university adult education, having regard to the economic position of Great Britain. Generally the reports indicate an increasing concern with standards of work and an increasing response by the more serious students to the demands made upon them. While every extra-mural department has been paying increasing attention to standards of work, the figures show a slight decline, on averages, from previous levels, and it appears that here, and elsewhere, there is a greater range of performance than usual between the good and the less satisfactory students. Moreover, while the number of classes in Great Britain has greatly increased, the average enrolment in classes has decreased, and it appears to be more difficult to recruit students for long courses of study.

A distinctive feature of liberal adult education in Great Britain has been its rejection of patently utilitarian studies; but there are indications that in certain subjects—notably the social sciences and industrial relations—the offer of a qualification might stimulate demand. Examinations and qualifications, however, are exceptional features of extra-mural work, though, at least in longer courses, serious work is expected of students, and it is a tribute to their zeal that so much should have been done.

As regards present difficulties, the report suggests that conditions of full employment are not conducive to wide interest in adult education among manual workers. While radio and television are probably its strongest rivals, television is not regarded as necessarily harmful to adult class-work. More use could probably be made of both television and sound-broadcasting as supplements to class teaching, and some questioning of the traditional methods of both organization and teaching is reported. There are signs that different approaches are already being made; but the traditional type of course is provided for the kind of student which is the particular concern of the Workers' Educational Association. The tutorial class was originally devised as a preliminary training for 'workers' deprived of any chance of more than merely elementary schooling, who wished to prepare themselves for the discipline of a course of university study. It rapidly became a substitute for both secondary and higher education for all those whose schooling had been restricted, and as such did notable work. It has now also become a course of study for those who have had reasonable educational opportunities, but who wish to take their education further or pursue some particular interest or study under guidance. The report gives no suggestion as to the Council's own views concerning the decisions which should be taken if economy enforces re-orientation or re-organization of extra-mural work. It indicates, however, that the university departments are fully alive to the issues involved, and the figures given in this report and its survey of subjects of study should materially assist an objective appraisal of the scope and functions of extra-mural work and adult education in the new context.

CARNEGIE UNITED KINGDOM TRUST

REPORT FOR 1952

In spite of continuing restrictions on capital expenditure, the thirty-ninth annual report* of the Carnegie United Kingdom Trust for 1952 reports good progress with several projects which involved building, notably for the rehousing of the Scottish Central Library and the provision or improvement of village halls. A building licence has also been granted for the Cheshire Foundation Home for the Sick, and it is hoped that the erection of a completely new home, specially designed for its purpose, and which may serve as a model for similar social enterprises elsewhere, will now proceed. A licence has also been granted for the boys' home to be provided by the West Ham Central Mission, and work started in November on this experiment with a country home for boys who had been in trouble or were likely to run into it. Grants during the year totalled £112,667, and the Trust work now appears to be proceeding on an adequate scale after the straitened years of the Second World War. In continuance of earlier surveys of juvenile delinquency, the Trustees have appointed Mr. John Mack, Stevenson lecturer in citizenship in the University of Glasgow, to make a survey of agencies active in this field and the difficulties which confront them. Mr. Mack was particularly asked to direct attention to any gaps in existing services and to indicate any effective action the Trustees might take by initiating genuinely pioneer work, whether preventive or remedial. Pending this report, the Trustees have already concluded that their most effective contributions will be found in their traditional field of practical experiment and demonstration.

---

* Carnegie United Kingdom Trust. Thirty-ninth Annual Report, 1952. Pp. 32. (From the Trust, Dunfermline, Fife.)

While the Trust may plan projects and make specific assignments to selected institutions, it will not make grants to existing institutions in respect of their work as a whole, nor interest itself in purely local projects. The Trustees also conclude that juvenile delinquency is only one aspect of the much wider problem of family welfare. The term 'juvenile delinquency' will no longer be used for describing a special branch of Trust interest; any such schemes will from now onwards be included under "Community Services and Social Welfare".

The Trustees record that the actual expenditure on village halls increased from less than £12,000 in 1951 to more than £17,000 in 1952, and they express the hope that all the promises made, totalling £80,000 in respect of eighty-four schemes, will have been fulfilled before the end of the present quinquennium. Full reports on two experiments in rural case-work, in Oxfordshire and in parts of Northumberland and Durham, indicate the reality and urgency of problems of family welfare in the countryside and the serious lack of co-ordination of effort among the agencies concerned with welfare services. Two schemes in the programme of the Family Welfare Association are still in an early stage; but the work of the Family Service Units has now extended to Birmingham, Leicester, Sheffield and York and in cordial relations with the local authorities concerned.

Under 'Education and Youth Services" a start has been made with the Taunton Museum scheme, which is distinguished for the quality of its collections and by the housing of them in a historic building. The Trust has provided £6,000, chiefly for the provision of cases and other display material, while the Pilgrim Trust has granted £3,000 for repairs to the fabric. Proposals for reorganization and improved display at thirteen other local museums have also been approved, and a grant has also been promised to the Outlook Tower Association of Edinburgh for the reorganization of the Scotland Collection in the Outlook Tower. A special and final grant of £7,500 was made to the National Central Library, and good progress was made during the year with the development of the machine designed to enable sighted people to communicate with those who are both blind and deaf. An investigation was also sponsored into the reactions of youthful audiences to films of various types.

INSPECTORATE OF FACTORIES IN GREAT BRITAIN

ANNUAL REPORT FOR 1951

A FEATURE of the annual report of the Chief Inspector of Factories for the year 1951 (Cmd. 8772; London: H.M.S.O., 1953; 6*s*. 6*d*. net) is a brief historical survey of changes in the industrial picture, so far as safety, health and welfare are concerned, during the fifty years since the consolidating Factory and Workshop Act was passed in 1901. Many changes in industrial location have taken place, and road transport has revolutionized the siting of factories, while the ever-increasing use of bicycles, omnibuses and other transport for the journey to work has made it much less essential to have the factory immediately close to the workers' homes. Many small firms have been amalgamated or swallowed up into large combines or have disappeared, but the great bulk of premises under the Act remain small; for example, 90 per cent of the locksmith work in the Black Country is still carried on by small family businesses, only two factories employing more than a thousand and only eleven more than a hundred, most of them employing less than a dozen. Most chain-makers employ less than twenty, and in their works the only step made in mechanization is the substitution of electric for hand blowers.

The number of factories without power has declined continuously from 137,648 in 1901 to 26,464, while those with power are now 212,245 compared with 95,664 in 1901. Mechanization, moreover, has eliminated much of the grinding load of hard dirty work and heavy lifting, and the changed attitude to mechanization is illustrated by the advertisements of a large bakery, which in 1901 claimed that "all bread was made by hand" and in 1951 boasted of bread "not touched by the human hand". The external aspect of factories has changed considerably, as has the composition of the labour force; but a major contribution to the greater cleanliness of to-day has been made by the greater variety of paints available, and the use of vacuum cleaners and of more suitable floorings. The much better illumination of recent years has also been a valuable stimulus to cleanliness and good housekeeping, as have the provisions of the Factories Act, 1937, which made compulsory weekly cleaning and the daily removal of refuse.

All reports agree that improvements in lighting are among the most important benefits of the past fifty years; but although regulations made under the 1901 Act laid down a standard for sanitary accommodation, poor accommodation, badly maintained, is still found in multiple buildings in large towns. Although few local authorities carry out routine inspections, relations with the local authorities appear to be much more friendly than at the beginning of the century. The standards of air space were raised by the Act of 1937 to 400 cu. ft. per person from the 250 cu. ft. of the 1901 Act; but while much remains to be done in regard to process steam, great advances have been made in ventilation, more particularly in the application of local exhaust to remove dangerous dust or fumes. New risks, however, continually arise, and where the sanctions of the general law and voluntary action are insufficient, each new hazard has been dealt with by special regulations. Every year, too, brings fresh reports of improved methods of mitigating or eliminating high temperatures in such trades as laundries, glass works or steel works, and also of improved methods of securing adequately warm temperatures.

Already in 1901, though the steam engine was still the main driving-force in industry, in spite of considerable inroads by the gas engine, inspectors were commenting favourably on the rapid development of electric power; and during the past fifty years all other forms of motive power have gradually declined. The individual drive and the sectionalization of transmission machinery have greatly reduced the dangers from revolving transmission machinery, and during recent years much attention has been given to the spacing or re-spacing of looms. A great deal has been done since 1901 in the provision of guards; but, in spite of the further obligation of the 1937 Act in regard to fencing dangerous machinery, occupiers still complained in 1951 that they were obliged to add to the fencing of many machines. Legal provisions regarding the reporting of accidents have varied during the years so that no valid conclusions can be drawn from a comparison of the 1,035 fatal accidents and 82,725 non-fatal accidents in 1901, with the corresponding figures of 944 and 159,693 in 1925 and 828 and 182,616 in 1951. Moreover, inspectors have sought increasingly to foster a positive attitude to accident prevention by stressing the importance of training and organization for safety.

Deaths and serious injuries from works fires, as distinct from burns from local sources, have been rare throughout 1951, and in all trades with special risks to health the records and memories of fifty years show a similar pattern. First there was the gradual, and sometimes grudging, realization of the source of danger to health, powerfully stimulated by the work of the medical inspectors and by individual research carried on by enlightened firms; search was then made for substitutes for the dangerous materials, with experiments in their use and special inquiries, followed, wherever agreement on voluntary action could not be obtained, by prohibition or control by special regulations. New techniques learned by sometimes unwilling management and men brought unexpected success after initial hostility to new materials. Where the dangerous material could not be eliminated, progress has been by way of total enclosure of the plant or by fitting local exhaust ventilation, with special provision of facilities for washing, protective clothing and regular medical examination. In the chemical industry enormous advances have been made in improving atmospheric conditions by exhaust ventilation, condensing plants and dust filtration units; but the increased use of inflammable and toxic solvents in the boot and shoe trades has brought new risks which are not yet completely removed. As a result of the introduction of low-solubility and leadless glazes, for the first time since records were kept there were no cases of lead poisoning in the Stoke district in 1944, and in 1947 the Pottery (Health) Regulations made the use of raw lead glaze illegal.

The biggest improvements in welfare—a word unknown to the 1901 Act and owing its legal existence to welfare orders made under the Police, Factories, etc. (Miscellaneous Provisions), Act of 1916—have come during the past ten years. Canteens were rarely found before 1914, but are now accepted as a necessity by most firms and workers, in spite of complaints, sometimes unjustified, about the quality of the food or service. In the same period has come a strong movement towards all forms of joint consultation, while throughout the half-century the attitude of management generally has greatly changed. Washing facilities were a luxury at the beginning of the century and only became compulsory in all factories under the 1937 Act. Each year since 1945 has recorded increased effort to give sufficient washing accommodation in attractive surroundings; but much less has been done to bring about really first-class cloakroom accommodation. In 1901 also the provision of protective clothing was rare. Now it is increasingly provided by firms as and when the process appears to need such clothing, and overalls are now often provided as a part of the works scheme for good appearance and good discipline. Outside the factory it is increasingly difficult to guess the type of work carried on by persons one meets in the streets.

No feature of the past half-century has been more striking than the reduction of working hours. In 1901 the usual working week was about fifty-five hours in most trades, the 1901 Act allowing sixty hours for women and young persons in non-textile factories, with a twelve-hour period from Monday to Friday and an eight-hour period on Saturdays. The working day in the Midlands and North of England was usually 6 a.m. to 6 p.m., with half an hour for breakfast, one hour for the midday meal and no authorized short breaks. Partly as the result of scientific study of fatigue, from 1918 the forty-eight hour week came to be recognized as normal and received legal sanction as a maximum for women and young persons more than sixteen in the 1937 Act. The five-day week which gained popularity in the 'thirties, particularly in the new industries in the South of England, became almost universal after the Second World War except in a few trades. The harsh asperities of shift-work have also been greatly softened.

At the beginning of 1902 there were ninety-five inspectors, including thirty-eight junior inspectors, and about thirty-four inspectors' assistants, as well as a principal lady inspector and a staff of eight lady inspectors. At the beginning of 1951 there were 322 inspectors and more than fifty vacant posts. The composition of the inspectorate had also changed. In place of the one medical inspector of 1901 there was a senior medical inspector and twelve medical inspectors, while the electrical inspector first appointed in 1902 has now been succeeded by a senior electrical inspector and thirteen electrical inspectors. The one engineering adviser of 1901 was the predecessor of the eighteen inspectors in the present engineering and chemical branches under the senior engineering and the senior chemical inspectors. Prosecutions in 1901 were more numerous but were largely for illegal employment of one kind or another, which does not occur on any scale at present. The basic principles on which inspection has been founded appear to have changed little, and the inspector's main task is still in the factories.

As regards the year 1951, the report expresses the view that the need for economy in the use of power, materials and labour compels a constant striving for greater efficiency which, although not always ensuring higher standards of safety, health and welfare, tends on the whole to improve working conditions. Those points of some general interest which emerge are, first, the establishment of a communal health service in one of the oldest trading estates in England which has assisted a factory manufacturing basic lead carbonate and lead nitrate in improving health conditions. Steps have been taken to equip a laboratory at the London School of Hygiene and Tropical Medicine, as an extension of this side of the health service, and a chemist has been engaged to undertake, *inter alia*, the estimation of lead in samples of air collected by the health engineer. The second matter is the attention given to radiological developments in industry. Special visits to representative factories using X-rays for the radiographic, fluoroscopic or crystallographic examination of castings and other materials have indicated that a very high standard of equipment, installation and use prevails. The question of protection in handling the large services of up to and just over a curie of cobalt-60 now available from Harwell, however, has caused some concern, and although no new permanent applications of radioactive tracers to routine industrial factory processes were reported during the year, it is likely that this new technique will soon be widely applied. The third point is further evidence of the capacity of persons more than sixty years of age to do useful work in industry without increased liability to accident.

THIRD INTERNATIONAL CONGRESS ON GLASS

THE Third International Congress on Glass was held in Venice during June 29–July 2, associated with the International Commission on Glass, the annual meeting of which was held on July 3. 179 delegates attended from twenty countries; they included 65 from Italy and 22 from Great Britain.

The Congress was organized by a Committee of the Italian Glass Manufacturers Federation. At the opening meeting of the Congress, Principe Giovanni Ginori Conti, who is president of the Federation, was inducted as president of the Congress by Dr. B. P. Dudding in his capacity as president of the Second International Congress on Glass held in London and Sheffield in 1936. This ceremony concluded with the presentation to Prince Ginori Conti by Mrs. W. E. S. Turner of a glass goblet on which the coat of arms of the Conti family had been engraved by Mrs. Turner, who is among the best of present-day English engravers.

The first day of the Congress was devoted to lectures on general subjects open to all members attending. Dr. M. Pasquato (Venice) reviewed the history of the glass industry centred in Murano since the eleventh century and traced the influence Venetian traditions have had on the artistic and industrial developments of the glass industry of the world. Prof. W. E. S. Turner (Sheffield) reviewed the growth of societies and research institutions not associated with specific industrial organizations since the formation of the Glass Research Delegacy in Sheffield in 1915 and the Society of Glass Technology in 1916. This was of particular interest to the Italian members, as negotiations have been proceeding between the Government and industry in Italy for some time, and a definite announcement was made at the end of the Congress reporting a decision to form both a technological society and in addition a research institute supported by government and industrial contributions. M. D'Argenlieu (Paris) reviewed the development of the use of glass in the building industry and raised some pertinent questions as to whether the glass industry had exhausted its contribution in this field. Prof. F. Roma (Bologna) described the sources of natural gas in northern Italy and discussed the conditions necessary to the efficient use in the glass industry. Prof. M. Czerny (Frankfurt am Main) indicated recent advances in the understanding of the problems of glass melting, and in particular the relative importance of heat transfer by radiation convection movements in the molten glass and conductivity through the glass. Mr. Edward Meigh (London) dealt with the interrelation of technology and management in modern industry, referring to the nature of the studies made in Great Britain under the auspices of the Institute of Industrial Administration and the British Institute of Management, with which the former is now amalgamated.

The following two days were devoted to specialized papers classified in four groups, three of which met simultaneously: Group I, Chemical and Physical Properties of Glasses; Group II, Glass Manufacture: Materials, Equipment, Methods; Group III, Form, Design, and Decoration of Glass; Group IV, History and Archæology.

About fifty papers were presented, and their efficient discussion was secured by making arrangements under which delegates could hear the speaker in any one of four languages, by a microphone and telephone service, which is becoming a general technique at international conferences.

In Group I several papers were presented which dealt with the modern physical concepts of the structure, and the slow changes which take place with time in the physical properties of glasses, depending on their previous thermal history. Another paper discussed the rate of reaction of glass-forming materials and the influence of the particle-size and the scale of operations on the rate of reaction.

In Group II, important and novel ideas concerning the methods employed to melt glasses and the techniques for exploring new designs of glass-melting furnaces were presented and led to extended discussions.

The artistic and archæological interests of glass brought together artists from eight different countries, and in the course of the discussions the influence of the artist on production of utilitarian glassware was emphasized.

Associated with the Congress were visits to Soc. Venez. Conterie e Cristallerie, Murano, to Vetrocoke at Porto Marghera, together with visits to museums, the Giorgio Cini Foundation on the isle of S. Giorgio Maggiore, and to the hydro-electric plant at Caverna, owned by the Società Adriatica di Elettricità. The Congress closed with a banquet at the Excelsior Palace at the Lido, given by the Associazione Nazionale degli Industriali del Vetro.

At the annual meeting of the International Commission on Glass held on July 3, Dr. B. P. Dudding, honorary secretary of the Commission, was elected president in succession to Prof. W. E. S. Turner, who has been president of the Commission since its formation in 1933. Prof. Turner was elected honorary president of the Commission. M. H. Vandecapelle, director of the Institut National du Verre, Belgium, was elected honorary secretary, and M. G. Henry, director general of the Union des Verreries Mécaniques, Belges, was elected honorary treasurer on the resignation of Dr. W. M. Hampton, of Chance Brothers, Ltd., Birmingham.

A tentative invitation was extended by the Swedish delegate to the Commission to hold its annual meeting in Sweden in 1954. No decision was taken in respect of the next Congress; but it is hoped that it will be held on the Continent in 1956.

ADVANCES IN METHODS OF STUDYING CLAYS

A MEETING of the Clay Minerals Group of the Mineralogical Society, held in the Department of Geology and Mineralogy, Marischal College, Aberdeen, during April 10–11, was mainly devoted to a discussion upon advances in methods of studying clays. On the morning of April 10, the laboratories of the Macaulay Institute for Soil Research and the Chemistry Department of the University were visited by members of the Group. At the scientific sessions the chair was occupied on the afternoon of April 10 by Dr. G. W. Brindley (University of Leeds) and on the following morning by R. H. S. Robertson (Glasgow).

Introducing the discussion, Dr. G. Nagelschmidt (Safety in Mines Establishment, Sheffield) reviewed the methods currently available for clay investigations, stressing particularly those of recent introduction. Following the course of a sample from its reception to the elucidation of its mineralogical composition, he referred to the following techniques and indicated the present limits to their application: deflocculation, clay mineral separation (for example, use of Clerici solution, sedimentation, electrophoresis, flotation, etc.), chemical analysis, light microscopy (including phase contrast), electron microscopy, X-ray examination, differential thermal analysis and infrared spectroscopy. Since many of these techniques, although at present very useful, are still not fully developed, more research into the basic principles upon which they are established is vital to the development of clay mineralogy.

The interpretation of X-ray diffraction patterns of interstratified minerals was considered theoretically by Dr. D. M. C. MacEwan (Rothamsted Experimental Station, Harpenden). Although previous work had established that curves showing the types of scattering to be expected from various mixtures of layers could be constructed and used for identification purposes[1], under certain circumstances (for example, for poly-component mixtures, or where segregation occurs), the construction of these curves becomes very laborious. The same applies to the alternative calculation of the appropriate Fourier transform; but by using an approximation, this latter method can, with very little calculation, give the requisite information as to the nature of the interstratified material[2]. Dr. MacEwan, replying to comments by Dr. Nagelschmidt and by Dr. H. P. Rooksby (General Electric Co., Ltd., Wembley), agreed that reflexions to higher angles are necessary to refine the transform, and that there is an analogy to scattering of X-rays by glasses. When R. Greene-Kelly and G. Brown (both of Rothamsted Experimental Station) questioned whether absorption difficulties, etc., would allow the requisite minimum number of orders of the basal spacing to be recognized in the diffraction patterns of, for example, many soil clays, Dr. MacEwan replied that he had as yet had little opportunity to apply the method to these materials.

Two papers from the Safety in Mines Research Establishment, Sheffield, dealt with quantitative X-ray methods. In the first, Dr. R. L. Gordon, O. G. Griffin and Dr. Nagelschmidt defined the criteria for internal standards to be of use in the photographic diffraction method, and demonstrated that both magnesium oxide and boehmite (γ-AlOOH) can be used for quartz. The former is best when large amounts of quartz (more than 30 per cent) are present, but the latter, for the comparison lines used, is not so good in the presence of kaolin. Some applications were described, and the results obtained were compared with those derived from chemical investigations. In the second paper, Dr. Gordon and Mr. Griffin described in detail a Geiger–Müller counter X-ray diffraction apparatus. Accurate measurement of line intensity rather than line position was aimed at, and was achieved by monitoring the primary X-ray beam by an auxiliary Geiger counter. Internal standards are unnecessary where accuracy of ± 10 per cent is adequate. In practice, this method is complementary to the photographic one. In the discussion Dr. Rooksby, Mr. Brown and Mr. Greene-Kelly referred to difficulties which might arise from differential absorption when using internal standards, but Dr. Gordon indicated that in the systems investigated all the minerals had approximately the same absorption coefficient. In reply to a further question by Mr. Brown, Dr. Nagelschmidt stated that, since the materials being investigated did not contain either boehmite or lepidocrocite, the former was a satisfactory internal standard. Dr. Gordon, commenting upon remarks by Dr. Brindley and E. W. Radoslovich (Cavendish Laboratory, Cambridge), stated that for the Geiger counter method a large sample is preferable to a small one, since the latter would entail narrowing the X-ray beam.

New techniques for preparing oriented-aggregate specimens for X-ray examination were reported in two brief papers. W. A. Mitchell (Macaulay Institute) has obtained parallel orientation of platy minerals by mechanical compression of the clay between two flat metal surfaces. The amount of orientation produced and the improvement in orientation for certain specimens over that produced by the conventional method were demonstrated by X-ray photographs. Mr. Brown described a semi-micro method utilizing special 'Perspex' centrifuge tubes with detachable bases, the clay settling on the flat inner surface of the base as an oriented aggregate. By using only about 1 mgm. of clay, the time necessary for preparation of the finished specimen from the original soil could be considerably shortened. In the discussion Mr. Greene-Kelly commented that the pressure technique would be very useful for platy minerals which would not disperse, and Mr. Mitchell reported that orientation had been obtained with soil clays containing only 5–10 per cent of platy minerals. Mlle. M. J. Deudon (I. R. Sidérurgie, Paris) and Dr. Brindley both referred to experiments with pressure, the latter reporting that high mechanical pressure could expel the water from hydrated halloysite and partially collapse the 'tubes'. The possibility of some orientation occurring during preparation of specimens for the Geiger counter X-ray diffraction apparatus, and consequent interference with results, was referred to by Dr. Rooksby.

Of two papers on differential thermal analysis, one dealt with technique and the other with interpretation of results. The apparatus for carrying out the analysis under inert atmospheres was fully described by Prof. A. L. Roberts and Dr. K. Carr (University of Leeds), who found this necessary where bituminous materials were involved, as these were not oxidized by hydrogen peroxide pre-treatment. The use of this modification for the quantitative determination of clay minerals in the presence of coal dust was demonstrated. In discussing the interpretation of the low-temperature endothermic peak of expanding minerals, Mr. Greene-Kelly reviewed previous theories[3] and pointed out their weaknesses. The occurrence of double peaks was shown to be normal where the hydration energy of the cation is sufficiently high for differences in mobility of desorbed water to be fully developed. When the hydration energy is below a certain value the mobility of the more tightly held water is apparently increased and the two peaks merge, as with sodium-, potassium-, rubidium- and cæsium-montmorillonite. In the discussion, the unsatisfactory nature of hydrogen peroxide as an oxidizing agent for organic matter was commented upon by Dr. R. C. Mackenzie (Macaulay Institute) and by D. A. Holdridge (British Ceramic Research Association, Stoke-on-Trent); the former reported the formation from certain soil clays of insoluble oxalates which interfere with thermograms, and the latter suggested the use of organic solvents for removing bituminous materials. Mr. Holdridge also remarked upon correlation between the size of the low-temperature exothermic peak and the amount of carbon as determined chemically. Dr. B. S. Neumann (Fuller's Earth Union, Redhill) inquired about Prof. Roberts's and Dr. Carr's experience with ferrous compounds in inert atmospheres. Welcoming Mr. Greene-Kelly's theory, Dr. Mackenzie said that the explanation of the previously anomalous Li^+ result is most encouraging. Dr. Brindley and he also referred to the possibility of diffusion being the peak-determining factor for materials other than montmorillonoids—for example, kaolins[4].

Possible methods which could be developed for the separation of clay minerals from mixtures were discussed and assessed by Miss K. R. Farquharson (Macaulay Institute). An attempt to use the reputed hydrophobic character of Deuel's montmorillonite-organic complexes[5] has been unsuccessful. The results of electrophoretic mobility measurements are now being applied using a constant-flow cell. Concentration of one component of a binary mixture has so far been observed, and further work is in progress. To a comment of Mr. Greene-Kelly upon the possibility of sorption of montmorillonite on kaolinite[6] at the pH values used (about pH 7), Dr. Mackenzie and Miss Farquharson replied that absence of electrolyte is necessary to avoid other undesirable effects. Mr. Robertson suggested that, because of rugosity[7] differences, separations might be possible by centrifugation of very dilute suspensions.

B. D. Mitchell (Macaulay Institute) and Dr. Mackenzie described a completely inorganic method for removing free iron oxide from clays, based upon the use of sodium hydrosulphite ($Na_2S_2O_4$)[8]. The effects of pH, time of extraction, etc., upon the efficiency of iron removal and upon the crystal lattice of various clay minerals were assessed, and a comparison made of the constituents brought into solution by this and by various other methods. Replying to I. H. Warren (English Clays, St. Austell), they indicated that neither sulphoxylates nor zinc hydrosulphite have yet been tested. The nomenclature of sodium hydrosulphite was discussed by Mr. Holdridge and Mr. Robertson; of the names hydrosulphite, hyposulphite and dithionite, the last was considered to be probably the least ambiguous. The effect of sodium hydrosulphite upon chlorites was referred to by Mlle. Deudon.

The last three papers, while not on the subject for discussion, demonstrated the results obtainable by current refined techniques. Mr. Brown gave evidence for a new clay mineral—a dioctahedral analogue of vermiculite—in a soil clay. The parent material is a dioctahedral mica. Data for the effect of various ions upon the relative intensities of the various X-ray reflexions were given. In reply to comments by Mr. Warren, Dr. Brindley and Dr. Nagelschmidt, Mr. Brown stated that the mineral reacted with ammonium ions after hydrogen peroxide treatment. Although five clay minerals were present, he considered all the reflexions described belonged to one mineral. W. A. Mitchell compared the weathering data with those for the formation of trioctahedral vermiculite in Scottish soils. A Geiger–Müller X-ray spectrometer together with exchangeable cation techniques similar to those described in the preceding paper were used by Dr. B. N. Rolfe (United States Geological Survey) and Prof. C. D. Jeffries (Pennsylvania State College) to elucidate the weathering sequence of mica in soils derived from Devonian shales and sandstones under different pedogenic conditions. The results were described in a communicated paper. The weathering sequence appeared to be: unweathered mica → 'mica intermediate' → hydrated mica (vermiculite); chlorite was present during initial stages of weathering. In the discussion, the evidence for chlorite and vermiculite and the relative stabilities of these minerals to heat treatment were discussed by Mr. Brown, W. A. Mitchell and Dr. Brindley. In the final paper, Dr. Brindley described recent X-ray investigations upon antigorite. Superimposed upon a band of scattering extending upwards from 4·6 A. has been observed a sequence of sharp, closely spaced lines, indicating a super-lattice. The dimensions have been calculated, and the significance of this finding in relation to Aruja's super-lattice and Onsager's interpretation was discussed. In discussion Mr. Robertson suggested that electron-micrographs might show if the super-lattice were caused by regular corrugations.

This discussion, while showing the need for further research into methods, also amply demonstrated the wealth of information available from present techniques—and especially indicated that only by application of all techniques available can a full understanding of the mineralogy and properties of any clay be obtained.

In a report of a previous meeting of the Clay Minerals Group held in Stoke-on-Trent during November 7–8, 1952 (see *Nature*, 171, 681; 1953), the statement on p. 682, second column, lines 18–16 from the bottom should read: ". . ., only dioctahedral components with the charge in the octahedral layer (that is, the montmorillonite type) will not swell".

SEPARATION OF CALF THYMUS DEOXYRIBONUCLEIC ACID INTO FRACTIONS OF DIFFERENT COMPOSITION

By PROF. ERWIN CHARGAFF, DR. CHARLES F. CRAMPTON and MISS RAKOMA LIPSHITZ

Department of Biochemistry, College of Physicians and Surgeons, Columbia University

IN the light of current conceptions, a preparation of deoxyribonucleic acid, which may be presumed to be an important component of the genetic material, could be regarded as consisting of many chemically different, though closely related, individuals, the constant composition of the whole being a statistical reflexion of the unchanging condition of the cell[1]. The composition, with respect to the distribution of

[a] The contents in deoxyribo- and pentose nucleic acids were determined colorimetrically with highly purified specimens as the reference standards[1]. Phosphorus was estimated by a colorimetric procedure[15], protein by an adaptation of the biuret reaction with crystalline egg albumin as the standard. ε(P), the atomic extinction coefficient with respect to phosphorus[16], was measured in 0·1 *M* phosphate buffer of *p*H 7·1. η_{sp}(P) is the specific viscosity (Ostwald–Fenske viscosimeter, outflow time for 0·1 *M* NaCl 62·7 seconds at 29·5°) divided by the molarity of the solution with respect to P; solutions in 0·1 *M* NaCl, containing about 15 γ of P per c.c., were employed.

[b] The salt concentrations in Experiments I to III were estimates, in Experiments IV and V chloride was determined titrimetrically[17]; in Experiments VI and VII the NaCl concentration was adjusted, as described in the text.

[c] The figures in parentheses (Experiments I to III) are based on the phosphorus distribution in the listed nucleic acid fractions. All other figures represent the quantity of P found in the particular extract as per cent of the total nucleohistone P subjected to fractionation.

[d] The actual total average recovery of moles of nitrogenous constituents per 100 gm.-atoms of P is indicated in the first column. The mean proportions of each constituent have been corrected for a 100 per cent recovery, in order to facilitate comparison.

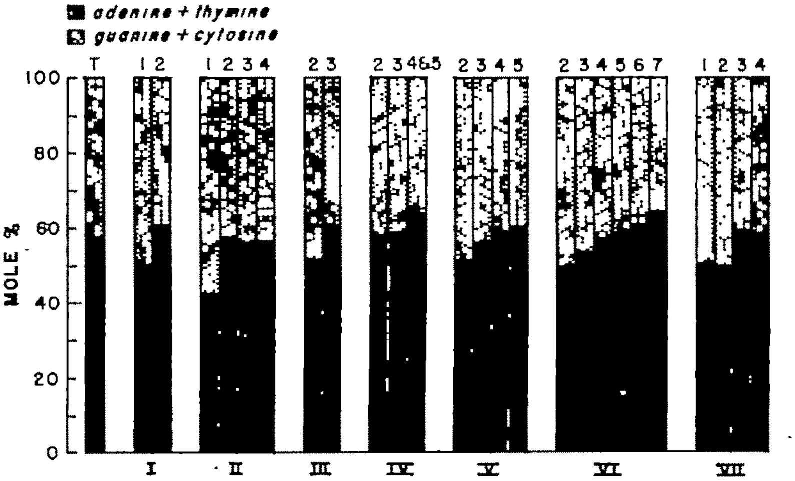
purines and pyrimidines, of deoxyribonucleic acid preparations isolated from the same species is indeed remarkably constant, though far-reaching species differences have been observed frequently[2-5]. As extreme examples of what we have termed the *GC* and *AT* types, respectively[4], the molar proportions of adenine to guanine may be quoted which amount to 0·4 in the deoxyribonucleic acid of the avian tubercle bacillus[6], but to 1·9 in the corresponding preparation from the sperm of *Paracentrotus lividus*[7]. An intermediate type, containing all nitrogenous constituents in nearly equimolar quantities, has been encountered only in *E. coli*[8,9].

The composition of the deoxyribonucleic acid of calf thymus is of particular relevance to the topic to be considered here. Twenty-one specimens of this nucleic acid, prepared by several procedures, showed no more than minute deviations in composition. The following mean proportions in moles of nitrogenous constituent per 100 gm.-atoms of phosphorus (with the standard error in parentheses) were found[10]: adenine 29·0 (0·2); guanine 21·2 (0·2); cytosine (including the small amount of 5-methylcytosine occurring in this nucleic acid[11]) 21·2 (0·2); thymine 28·5 (0·2); molar ratio of adenine + thymine to guanine + cytosine 1·36. Regularities applying to all deoxyribonucleic acids studied in this laboratory have been pointed out before: the sum of purine nucleotides equals that of pyrimidine nucleotides; the ratio of adenine to thymine is nearly 1, and so is that of guanine to cytosine (+ 5-methylcytosine); the proportion of amino groups to enolic hydroxyls is around 1·5 [2-4].

Although the possibility that a deoxyribonucleic acid preparation from a given species represents a mixture of many different individuals has been discussed before[1,3,4], records of attempted fractionation are not numerous. Preparations isolated from the cell by non-destructive procedures apparently are not separable into specimens of different composition by fractional centrifugation[11] or adsorption on charcoal[12]. Nucleic acid preparations extracted from tissues at a very high temperature (85°) have been separated into two fractions differing in their solubility in physiological saline and in the extent to which previously administered carbon-14 had been incorporated into the various purines and pyrimidines[13,14].

In the course of studies on calf thymus nucleohistone, which will be presented on a later occasion, it was observed that deoxyribonucleic acid fractions of divergent purine and pyrimidine contents could be isolated by what may be described as fractional dissociation of the nucleoprotein.

The essential steps in the fractionation experiments, which were carried out at about 4°, the results of



Composition of calf thymus deoxyribonucleic acid fractions (in moles per 100 gm.-atoms of phosphorus). The experiments and fractions are numbered as in Table 1. The first column (*T*) indicates the average composition of the total deoxyribonucleic acid[19]

which are summarized in Table 1, were as follows. (1) Fresh, minced calf thymus tissue, washed with physiological saline and then with small portions of distilled water, was extracted with a five-fold weight of distilled water. (2) The aqueous nucleohistone solution, comprising about 90 per cent of the total nucleic acid of thymus, was treated in a high-speed mixer for five minutes with one-half volume of a mixture of chloroform and *n*-octanol (9 : 1 by volume)[18]. Centrifugation at 20,000 *g* for fifteen minutes produced a loosely packed gel and an opalescent supernatant solution which was twice more treated with chloroform–octanol. (3) The combined gels were extracted stepwise with sodium chloride solutions of increasing concentration, each treatment in the high-speed mixer being followed, after an interval of at least thirty minutes, by centrifugation at 2,000 *g*. (4) The precipitate resulting from the addition of two volumes of ethanol to each extract was dissolved in 10 per cent sodium chloride, deproteinized by repeated treatment with chloroform–octanol, and the aqueous solution of the nucleic acid was, after re-precipitation with alcohol, freed of electrolytes by dialysis and of water by evaporation *in vacuo* in the frozen state. In Experiments VI and VII (Table 1) steps 2 and 3 were modified: after the treatment of the aqueous nucleohistone solution with chloroform, a known salt concentration was established by the addition of solid sodium chloride; the mixture was stirred for five minutes, kept for 30 minutes and then centrifuged for the same period at 2,000 *g*. The amount of salt and of water remaining in the sediment could be estimated from the volume of the supernatant solution. In all subsequent extractions the desired sodium chloride molarity and a volume of water equal to that of the original nucleohistone solution were maintained by the addition of sufficient quantities of water and salt.

The principal analytical results are assembled in Table 1. Distilled water extracted only small amounts of deoxyribonucleic acid (for example, fractions III-1, IV-1, V-1); and these specimens, as also occasionally the first salt extracts (for example, fraction VI-1), were contaminated with pentose nucleic acid. Not all such minor fractions have, therefore, been tabulated, though they, as well as the residues of the final extraction, were included in the establishment of phosphorus balances. In Experiment V 92·4 per cent of the total nucleohistone phosphorus could thus be accounted for, in Experiment VI 89·3 per cent, and 84·2 per cent in Experiment VII. Fraction II-1, as isolated initially, contained 3·7 per cent of pentose nucleic acid and was contaminated with non-phosphorylated material; it was purified by treatment with charcoal[13]. The values for individual purines and pyrimidines are averages of at least two independent hydrolysis experiments in each of which 12 to 24 determinations of each constituent were performed. The hydrolysis and estimation procedures have been described previously[19]. In many instances hydrolysis with perchloric acid[20] also was employed.

The results of the fractionation are most clearly seen in the figure in which the molar sums of adenine and thymine found in each significant fraction are contrasted with the corresponding sums of guanine and cytosine. It will be noticed that the gradual extraction of the nucleoprotein with salt solutions of increasing strength yields a series of nucleic acid fractions with diminishing concentrations of guanine and cytosine and rising concentrations of adenine and thymine. The equimolarity of each pair of constituents and of total purines and pyrimidines is, however, maintained[8] (see Table 1). Fractions II-1 and VI-7 show the greatest divergence from the composition of total calf thymus deoxyribonucleic acid; but the trend is unmistakable in all cases. When the increments contributed by each fraction are computed, an average composition results which is almost identical with that of total calf thymus deoxyribonucleic acid quoted at the beginning.

The study of the composition of the various fractions was not limited to the four major nitrogenous constituents listed in Table 1. It appeared of particular interest to investigate the distribution of 5-methylcytosine which is known to occur, mostly as a minor component, in many deoxyribonucleic acids[11] and has been isolated from that of calf thymus in the form of its nucleotide[21]. For the quantitative determination of this pyrimidine, hydrolysates of the fractions collected in Experiment VII (20–25 mgm. of nucleic acid in 0·5 ml. of concentrated formic acid) were subjected, in 0·04–0·06 ml. aliquots, to paper chromatography with distilled water which, in the arrangement described previously, permitted the separation of purines from pyrimidines. The purine zones then were cut off and the irrigation was continued with a mixture of six volumes of *n*-butanol and one volume of 0·1 *N* ammonia[19]. The results summarized in Table 2 show significant divergences in the concentration of this satellite in the several fractions and may be considered as additional proof that the fractionation of the deoxyribonucleic acid of calf thymus has been achieved. The average contents of 5-methylcytosine computed from the figures reported here are in good agreement with its concentration in total thymus nucleic acid[11,22].

The fractionation presented here rests probably on differences in the stability of the bonds between

Table 2. 5-METHYLCYTOSINE DISTRIBUTION IN FRACTIONATION EXPERIMENT VII*

	Fraction 1	Fraction 2	Fraction 3	Fraction 4
Moles per 100 *gm.-atoms of P*				
Pyrimidines recovered	41·2	52·2	45·7	46·3
Corrected mean proportions				
Thymine	24·2	24·0	29·0	28·7
Cytosine	23·0	23·4	19·8	21·3
5-Methylcytosine	1·9	2·7	1·2	0
Molar ratio				
Thymine to 5-methylcytosine	12·7	8·9	24·2	
Cytosine to 5-methylcytosine	12·6	8·7	16·5	

* The moles of pyrimidines actually found per 100 gm.-atoms of phosphorus are reported in the first line. The mean proportions of each constituent have been corrected on the assumption that one-half of the nucleic acid phosphorus is contributed by the pyrimidine nucleotides. In one hydrolysis experiment with Fraction 4 a minute amount of 5-methylcytosine (about 0·6 mole) was found.

nucleic acid and protein. The extent, however, to which both partners, the nucleic acids and the proteins, are concerned in this behaviour, cannot yet be evaluated; nor can it be decided whether the various conjugated proteins, of which nucleohistone presumably is composed, share the same protein or whether numerous combinations of different nucleic acids and different proteins occur. As regards the nucleic acids themselves, which, as has been shown here, can be separated into fractions of different composition, the following list of possibilities is by no means exhaustive. (1) The fractions are degradation products; an unlikely assumption not borne out by the spectroscopic and viscosity measurements provided in Table 1. Moreover, the isolation procedures did not exceed in vigour those usually employed for the isolation of nucleic acid. (2) Deoxyribonucleic acid is a mixture either of polyadenylic, poly-guanylic acids, etc., or of purine polynucleotides and pyrimidine polynucleotides, or of copolymers consisting exclusively of adenylic and thymidylic acids on one hand, and of guanylic and cytidylic acids on the other. These assumptions are contradicted by most of the available chemical evidence. (3) A slightly more plausible formulation may be seen in the view that deoxyribonucleic acids are composed of varying quantities of two extreme varieties, one predominantly containing equimolar amounts of adenine and thymine, the other of guanine and cytosine. (4) The most likely supposition—and one receiving some support from the distribution of fractions, for example, in Experiment VI—is that one is dealing with a very large number of differently constituted individuals, with an entire spectrum of structural gradations, in which the regularities mentioned before are maintained.

The extension of the present observations to other fractionation studies will be described later. They may contribute better material for X-ray work; and it should be of particular interest to apply them to deoxyribonucleic acids that are active in inducing bacterial transformation.

One of us (C. F. C.) took part in this work as a Fellow of the National Foundation for Infantile Paralysis. The research was aided by grants from the American Cancer Society on the recommendation of the Committee on Growth of the National Research Council and from the Rockefeller Foundation.

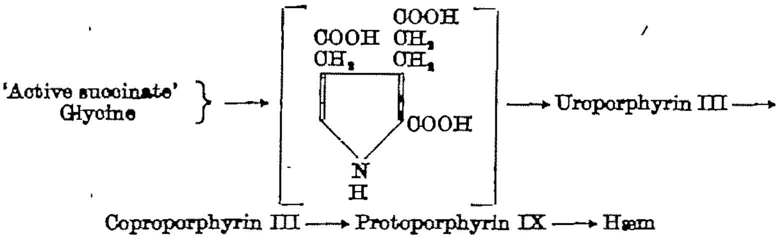
PORPHOBILINOGEN AS A PORPHYRIN PRECURSOR, AND INTERCONVERSION OF PORPHYRINS, IN A TISSUE SYSTEM

By J. E. FALK, E. I. B. DRESEL and
C. RIMINGTON

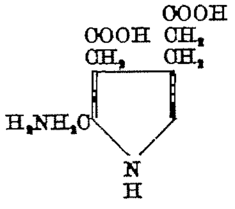
Nuffield Unit for Research in Pyrrole Pigment Metabolism,
Department of Chemical Pathology, University College
Hospital Medical School, London, W.C.1

THE sequence of events in the biosynthesis of hæm might be supposed, from evidence hitherto available, to follow a scheme such as:



(I)

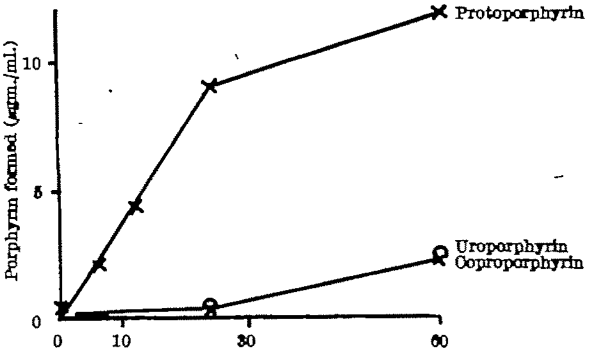
The evidence can only be summarized briefly here: utilization of glycine and 'active succinate' in the formation of hæm has been established by the work of Wittenberg and Shemin[1], Muir and Neuberger[2], and Shemin and Kumin[3]. The requirement of glycine for the biosynthesis of free protoporphyrin has been shown by Bénard, Gajdos and Gajdos-Török[4]; in addition, Dresel and Falk[5] have established that eight α-C atoms of glycine are incorporated into each molecule of protoporphyrin synthesized, just as has been found for hæm synthesis[1,3]. The conversion of radioactive uroporphyrin III to protoporphyrin has been demonstrated by Salomon, Richmond and Altman[6], using rabbit bone-marrow homogenates. The place of coproporphyrin in the sequence, though chemically feasible, is supported only by indirect evidence (cf. Watson[7]). That protoporphyrin is converted to its ferrous complex, hæm, by tissues might appear self-evident; but this conversion has not yet been demonstrated experimentally. It is quite conceivable, though iron–porphyrin complexes other than hæm are not found, that a transient iron complex of a porphyrin other than protoporphyrin may be the true hæm precursor.



(II)

An intermediate such as the pyrrole tricarboxylic acid resulting from condensation of two molecules of 'active succinate' with glycine (I) was indicated by the results of Shemin and Kumin[3]. The probable structure for porphobilinogen (II) recently advanced by Cookson, Rimington and Kennard[8], following its isolation by Westall[9], is very similar to this pyrrole tricarboxylic acid. This similarity, together with the facts that porphobilinogen is excreted in disturbances of porphyrin metabolism[10] and is converted easily and non-enzymically to uroporphyrin[8,9], all suggested that it might be a normal porphyrin precursor. The preparation of hæmolysed chicken erythrocytes, being used in this laboratory[11,12] for studies of the mechanisms of blood pigment biosynthesis, offered a very favourable system for the direct investigation of this possible role of porphobilinogen, and also of some of the porphyrin interconversions shown in (I).

On incubation with the hæmolysate in air, porphobilinogen was converted to proto-, copro- and uroporphyrins as shown in the accompanying illustration. At a concentration of about 10 μgm./ml., about 60 per cent of the porphobilinogen was converted to protoporphyrin; no significant amount of porphobilinogen remained unchanged, although 94 per cent of that added was recovered after incubation in the same way with a boiled hæmolysate. Some of the porphobilinogen has thus not been accounted for; but it is probable that a considerable proportion of this was converted, *via* protoporphyrin, to hæm. We are planning to investigate this with the aid of radioactive porphobilinogen. Porphobilinogen may also have been lost through its conversion to porphobilin and other non-porphyrin pigments, or to colourless porphyrin precursors (cf. Brockman and Gray[13]); these possibilities are being investigated. As might be expected, the conversion of porphobilinogen to protoporphyrin is not inhibited by 2 : 4-dinitrophenol, which effectively inhibits the synthesis of protoporphyrin from glycine[5]. It was of some interest to determine whether the enzymes concerned in the conversion of porphobilinogen to porphyrins are present in solution, or whether they are associated with the solid material (ghosts, etc.) obtained when the hæmolysate is centrifuged at high speed (15,000 *g* at 2°). The solids were washed twice with, and resuspended in, 0·9 per cent potassium chloride, and the fate of porphobilinogen on incubation with the solids and supernatant was studied. Whereas the recombined fractions brought about a 60 per cent conversion of porphobilinogen to protoporphyrin, identical to that obtained with the unfractionated hæmolysate, porphobilinogen incubated with the solids alone was all recovered unchanged; incubation with the supernatant alone resulted in conversion of about 24 per cent of the added porphobilinogen to porphyrin, which was, however, mainly coproporphyrin.



Conversion of porphobilinogen to porphyrins. Hæmolysate (ref. 12) incubated 4 hr. at 38° C. with shaking in air

PORPHYRINS FORMED FROM PORPHOBILINOGEN UNDER AEROBIC AND ANAEROBIC CONDITIONS BY RED CELL HÆMOLYSATES

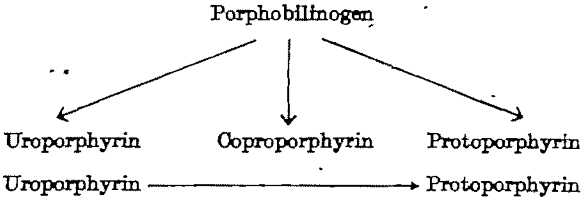
Incubation	Porphobilinogen recovered	Uroporphyrin	Coproporphyrin	Protoporphyrin
4 hr. air	2	0	1	61
4 hr. N_2	3	11	14	5
2 hr. N_2	20	15	8	2
2 hr. N_2, then 2 hr. air	2	1	11	47

Hæmolysate shaken at 38° with porphobilinogen (25 μgm./ml.). All figures are percentages of the porphobilinogen added

For its conversion to protoporphyrin, both decarboxylation and dehydrogenation of two of the propionic acid side-chains of coproporphyrin are necessary. It was possible that the dehydrogenation might require aerobic conditions; indeed, this was indicated by the finding of Bénard, Gajdos and Gajdos-Török[14], that blood from phenylhydrazine-poisoned anæmic rabbits formed mainly protoporphyrin when incubated with glycine aerobically, but predominantly coproporphyrin when incubated similarly under nitrogen. We have found that incubation of the hæmolysate with porphobilinogen under nitrogen results in an accumulation of uroporphyrin and coproporphyrin, the formation of protoporphyrin being greatly reduced. In an attempt to show directly the conversion of coproporphyrin to protoporphyrin, a flask was incubated under nitrogen for 2 hr., then aerated, and incubated in air for a further 2 hr. Protoporphyrin, in fact, increased greatly after the aeration; but, although uroporphyrin disappeared, the coproporphyrin content was little changed (see table).

The constitutions of the free porphyrins formed in these experiments were checked by paper chromatography in a lutidine–water system[15]; the porphyrins were also esterified, and the esters subjected to isomer-analysis by paper chromatography[16,17]. Both the uroporphyrin and the coproporphyrin formed from porphobilinogen behaved mainly as the III-series isomers.

As we had found conversion of porphobilinogen to uro-, copro- and protoporphyrins, it was interesting to attempt a direct demonstration of interconversion of these porphyrins. On incubation of pure uroporphyrin III (3 μgm./ml.) with the hæmolysate, 52 per cent was converted to protoporphyrin. This provides a direct confirmation of Salomon, Richmond and Altman's demonstration[6] of the same conversion by an isotope-tracer method. Incubation with pure coproporphyrin III (3 and 9 μgm./ml.) resulted in no significant formation of protoporphyrin, and most of the coproporphyrin was recovered unchanged.



(III)

The conversions we have so far shown are summarized in (III). These are end-results, and we do not yet know, for example, whether uroporphyrin on one hand and porphobilinogen on the other are converted to protoporphyrin *via* the other porphyrins or not. Further, though there is no doubt that the tissue can bring about these conversions, this alone does not prove that porphobilinogen or uroporphyrin are normal intermediates in the biosynthesis of hæm. An investigation into whether these substances are formed under conditions favourable for hæm synthesis might throw light on this problem. We have been able to isolate radioactive porphobilinogen, uroporphyrin and coproporphyrin from hæmolysates incubated with radioactive glycine in the presence of 'carrier' porphobilinogen, uroporphyrin and coproporphyrin, respectively. The possibility of contamination with radioactive glycine, or with radioactive protoporphyrin, was excluded. Thus we have shown that, besides protoporphyrin[11,12], porphobilinogen, uroporphyrin and coproporphyrin are all synthesized from glycine in the hæmolysate. These results will be discussed in greater detail elsewhere.

We thank Miss A. Benson and Mr. F. Grover for their skilled assistance, Mr. R. G. Westall for a gift of porphobilinogen and the Nuffield Foundation for making this work possible.

X-RAY SCATTERING EVIDENCE REGARDING THE PROTEIN–NUCLEIC ACID COMBINATION IN NUCLEOPROTEINS

By DR. D. P. RILEY and DR. U. W. ARNDT

Royal Institution, London, W.1

VARIOUS hypotheses have been advanced concerning the way in which the nucleoprotein complex is built up from its two components, nucleic acid and protein (histone or protamine). On one hand, it has been suggested that the combination of the two constituents is intimate and that the protein polypeptide chains are closely aligned with, or coiled around, the nucleic acid chains. The implication in these hypotheses is that the protein polypeptide chains are, at least partially, unfolded from the configuration existing in the separated protein molecules; several authors have suggested that this unfolding is complete and that the polypeptide chains have the fully-extended β-configuration. The most contrasted hypothesis is that the nucleoprotein molecule is simply an addition complex of protein plus nucleic acid held together, principally, by salt linkages. The protein moiety is considered to be essentially identical in structure with the separated fraction.

It occurred to us that a quantitative comparison of the X-ray scattering curves given by amorphous samples of nucleic acid, protein and nucleoprotein, respectively, might allow a decision to be reached about the nature of the combination, irrespective of any assumptions concerning the exact structures of the components. The intensity of scattering from an addition complex of two bulky macromolecules should, fairly exactly, be the sum of the intensities scattered separately by the two individual constituents. This would not be the case with small molecules, because of the relatively greater importance of interference terms; nor, for the same reason, would it hold for an intimate type of close combination of filamentous macromolecules, such as would be provided by intertwining. In such an instance, the scattering would show qualitatively new features not given by either component separately.

Through the kind co-operation of Prof. J. A. V. Butler and Mr. P. F. Davison, we have been able to investigate nucleoprotein specimens which they have separated from herring sperm and calf thymus with the minimum amount of chemical treatment[1], so that it is reasonably certain that the samples are native nucleoproteins and not reconstituted aggregates of components liberated during the extractions. In addition, the corresponding separated proteins and nucleic acids have been examined. The intensity curves reproduced in Figs. 1 and 2 were obtained from air-dry compacts of six specimens by means of a counter-spectrometer and refer to practically monochromatic copper $K\alpha$ radiation. All the curves have been put on the same normalized absolute scale by equating them at high values of $(\sin\theta)/\lambda$ (not drawn). The accuracy attained was about ± 2 per cent.

The additional curves drawn with broken lines were obtained by adding together the values for protein and nucleic acid in the proportions of 58 per cent histone + 42 per cent nucleic acid for the

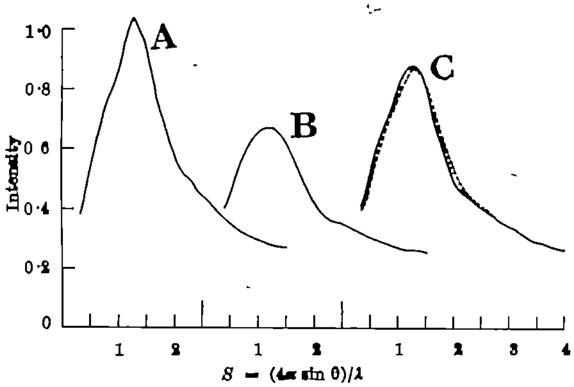

Fig. 1. Normalized X-ray scattering curves from herring sperm preparations: *A*, clupein sulphate; *B*, nucleic acid (Na salt); *C*, nucleoprotein. Dashed curve represents sum of 56 per cent *A* and 44 per cent *B*. Origins for *B* and *C* displaced to the right as indicated by the longer lines on the horizontal scale

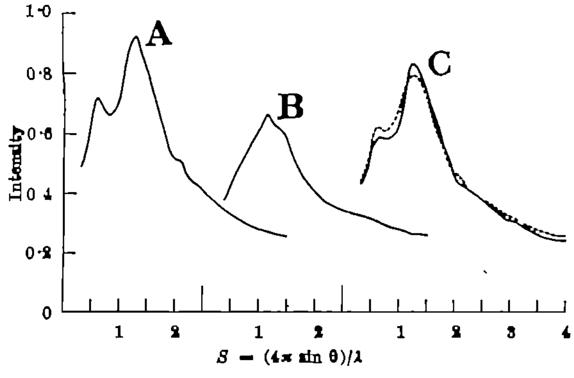

Fig. 2. Normalized X-ray scattering curves from thymus preparations: *A*, histone sulphate; *B*, nucleic acid (Na salt); *C*, nucleoprotein. Dashed curve represents sum of 58 per cent *A* and 42 per cent *B*. Origins displaced as in Fig. 1

thymus preparations and 56 per cent clupein + 44 per cent nucleic acid for the herring sperm samples. (These compositions are sufficiently exact and are derived from the nitrogen–phosphorus ratios obtained by analysis of the nucleoproteins.) They therefore represent the scattering to be expected if the nucleoproteins are simple addition products. As will be seen from the figures, the agreement with the intensity curves measured directly on the nucleoprotein specimens themselves is good.

In the case of the herring sperm preparations (Fig. 1), only one peak is observed, and the curves are rather featureless. Nevertheless, we would not expect the agreement between the summation curve and the observed nucleoprotein scattering to be as close as it is if the nucleoprotein were other than a fairly gross addition complex. In particular, we think that Watson and Crick's attractive suggestion[2] that the polypeptide chain is of the fully-extended β-type and wound in a specific and intimate way around the axis of the nucleic acid double-helix is unlikely to be true as regards this material in the form examined by us.

This is even more evident when the equivalent intensity curves (Fig. 2) for the thymus preparations are considered, as it is particularly difficult to account for the persistence of the inner 10-A. protein peak except by preserving the protein structure essentially intact in the nucleoprotein complex. Again, were the Watson–Crick hypothesis correct, one would expect scattering curves of similar type to be given by the two nucleoproteins: certainly, there would be no reason for a 10-A. peak to occur in the thymus material but not in that from herring sperm. The 10-A. peak is almost certainly due to the parallel grouping of several neighbouring polypeptide chains to form a bundle. Work not yet published in detail[3] suggests that histone possesses the α-helix structure of Pauling and Corey, although this assumption is not necessary to the present argument.

The agreement between the calculated and measured curves for the two nucleoproteins, while good, is not perfect. Part of the reason for this may be that the separated proteins were examined in the form of sulphates and the nucleic acids as the sodium salts, whereas in the native nucleoproteins these inorganic ions are absent. The discrepancy in the case of thymus preparations is, however, sufficient to require explanation, as no reasonable alteration in the proportions of the two constituent curves will lower the 10-A. peak and, at the same time, raise the 5-A. peak, to be coincident with the observed positions. It would appear either that the separated histone sample does not represent the totality of the protein moiety of the nucleoprotein or that its structure has been modified, although not greatly, in the course of extraction. It appears certain[4] that thymus histone is not a homogeneous protein, and various fractions with which we have been provided do, indeed, show differences in their scattering curves. The possibility of some degradation during extraction[5] must also always be present. Nevertheless, our results would not exclude the possibility that partial unfolding of the histone molecule occurs when it forms its addition complex with nucleic acid. By 'partial unfolding', we mean only that the parallel grouping of polypeptide chains is somewhat affected, but not the manner in which the chains themselves are coiled into a regular configuration, such as that of the α-helix.

It is of interest to note that the curves for the two sorts of nucleic acid are not absolutely identical, although they are closely similar. This observation must reflect differences in structure. Another fact worthy of remark is that, in the case of the air-dry 'amorphous' nucleic acids, no peak whatever appears corresponding to a parallel grouping of molecules. Such a peak, as was shown in earlier work[6], is a prominent feature of the scattering from aqueous gels of nucleic acid (sodium salt) over a very wide range of concentration, and the crystalline phase also exhibits diffraction lines which are the equivalent. The organizing role of water is obviously of great importance with this molecule and probably also with its natural complexes with protein. Therefore, it is not inconceivable that the conclusions reached in this paper would not apply to nucleoproteins in the living cell.

The investigation reported here forms part of researches supported by grants from the British Empire Cancer Campaign.

Cosmic Origin of Radiation at Radio Frequencies

THE recent identification by W. Baade and R. Minkowski of the intense discrete radio source in Cygnus as being an emission from two colliding galaxies[1] raises a number of interesting theoretical questions. In the first place, the only material likely to be seriously disturbed by such a collision is the diffuse interstellar material lying between the stars in these galaxies. Consequently, it would seem profitable to seek a process of generation of radio waves that takes place in extremely diffuse gas clouds. Secondly, processes of magnetic resonance requiring field intensities of many gauss, such as the Larmor precession, would seem to be excluded, since fields of this intensity could scarcely be maintained throughout regions of galactic dimensions.

It is natural to assume that the high velocity of collision of the two galaxies, perhaps of the order of 2,000 km. per sec., plays an important part in the generation of the radio waves that we receive from the Cygnus source. This view is supported by Minkowski's recent work[1] on the well-known source in Cassiopeia. The Cassiopeia source originates in a group of gaseous filaments within our own galaxy. Minkowski finds that these filaments show internal relative velocities up to 3,000 km. per sec., which, apart from the velocities of expansion of nova and supernova shells, is unprecedentedly large for motions within the galaxy. Mention of supernovæ recalls that the Crab nebula is also a discrete radio source, and that the material of this nebula also possesses high velocity, of the order of 1,000 km. per sec.

Now a high velocity probably implies a high electron temperature. Hence it is not certain that the radio emission owes its origin directly to motions of large masses: it may arise thermally as a result of high temperature. Of these two possibilities the thermal case is much the simpler to consider, and it is this case which forms the subject of the present communication.

The suggestion that the radio emission from such sources as those of Cygnus, Cassiopeia, and of the Crab nebula is of thermal origin may seem somewhat surprising in view of the objections that have frequently been raised against it[2]. Yet the suggestion derives an immediate plausibility from the circumstance that black-body emission in the metre wave-band would adequately explain the observed intensities of these sources. Thus two spiral galaxies colliding head-on at a relative speed of 2,000 km. per sec. must come to be surrounded by an ionized gas cloud with an electron temperature of order 10^8 deg. K. and with dimensions of order 10,000 parsecs. Black-body emission at the appropriate frequencies from such a cloud yields an intensity sufficient for the Cygnus source; indeed the intensity would be sufficient for the system to be detectable as a discrete radio source even if it were to lie at a distance of nearly 1,000 million parsecs, which is beyond the optical range of the greatest telescopes[3]. Or again, black-body emission at about 10^6 deg. K. would be sufficient to explain the observed intensity of the Crab—it being noted that an electron temperature of this order has been shown by Greenstein and Minkowski to be consistent with the optical spectrum of the Crab nebula[4].

The first difficulty that this suggestion has to overcome is that of providing a thermal source of radiation adequate to build up the black-body intensity in the metre wave-band. The second difficulty is to explain why the same process does not build up the black-body intensity in the centimetre wave-band.

The first difficulty arises because, in the absence of magnetic resonances, the only process of thermal emission that seems available is that due to electron-positive ion collisions. But the usual treatment of electron positive ion collisions yields a radiation-rate that is insufficient to maintain the black-body rate by a large margin—by a factor of roughly 10^3 in the case of the Crab, and by about 10^4 for two colliding galaxies. Accordingly, escape from the present difficulty would seem to depend on our being able to maintain successfully that the usual treatment of the electron-positive ion collision problem is in error, at any rate so far as the emission of radio waves in the metre band is concerned.

To consider this matter, we treat the case where the material consists of ionized hydrogen. First, we note that the usual treatment of this case yields a radiation-rate per unit volume which is proportional to n^2, where n is the average number density of hydrogen atoms: n is also the average number density of both protons and electrons, since the ionized gas is taken as having zero average charge density. The dependence on n^2 is easy to understand when the distance between electron and proton during collision is appreciably smaller than the mean inter-particle distance—we say that the number of collisions of a particular electron is proportional to the proton density n, and since there is an average of n electrons per unit volume, this immediately gives a radiation-rate per unit volume proportional to n^2. But how if the typical collision distance for the emission of radio waves is much greater than the mean inter-particle distance? How do we interpret the dependence on n^2 in this case?

To approach this question, we note that radiation arises from the acceleration of electrons in the Coulomb fields of the protons. A wave of frequency f arises mainly from accelerations that vary appreciably in a time $1/f$. In this time an electron moving with velocity v travels a distance v/f. Hence the emission of frequency f arises from accelerations that vary during the passage of electrons through distances of order v/f; that is to say, v/f gives the order of the collision distance for the emission of frequency f.

Now when v^3n/f^3 is large compared to unity, we must take account of fluctuations in the distribution of the protons and electrons. At any given time the number of protons within distance v/f from a particular electron will not usually equal exactly the number of electrons within this distance, although on taking a time average the two numbers become essentially equal in an uncharged gas. Stated otherwise, there will in general be a difference between the numbers of electrons and protons that are within distance v/f from a particular electron; and if the positions of the particles are at random, then by well-known considerations this difference must be of order $(v/f)^{3/2} . n^{1/2}$. Hence the electron is accelerated not by just one elementary charge but by $(v/f)^{3/2} n^{1/2}$ units of charge. Since the rate of radiation is proportional to the square of this acceleration, we obtain a rate per electron proportional to n; and consequently a radiation-rate per unit volume proportional to n^2, as before.

The clue to our problem lies in the foregoing. If the positions of the protons and electrons are not distributed at random, if a separation of charge has occurred for some reason, then the charge excess within distance v/f from a particular electron may considerably exceed $(v/f)^{3/2} n^{1/2}$. Indeed, in the case of a nearly complete charge separation, the electrons accelerate under the influence of $(v/f)^3 n$ units of charge—instead of under the influence of $(v/f)^{3/2} n^{1/2}$ units of charge as in the usual treatment. This increases the radiation-rate by $(v/f)^3 n$, which for $f = 10^8$ cycles per sec. gives a factor of about 10^6 in the case of two colliding galaxies (choosing v to correspond to an electron temperature of 10^4 deg. K.). This factor is of the order required to overcome the discrepancy mentioned above. Not only this, but the strong dependence on f shows that the present process of emission weakens rapidly as the frequency rises. This would seem to offer hope of overcoming the second of the difficulties mentioned above.

A slight modification of the above argument is required for the case of the Crab, since the material in this case is not essentially pure hydrogen (hydrogen being in low concentration). The modification does not alter the main feature of the argument, however: that an appreciable charge separation increases the rate of radiation by a large factor. It may be added that absorption processes increase correspondingly, the increase being such as to limit the radiation field to the Planck intensity.

It remains to remark on the cause of a separation of charge. It is well known that charge separation must occur when an ionized gas is in motion in the presence of a magnetic field; and a magnetic field, perhaps of order 10^{-6} gauss, is likely to be present in our case. There is therefore no difficulty in understanding, in principle, how charge separation can arise. Further considerations are, however, required in order to discover the conditions under which the charge separation may become nearly complete, as is necessary if the greatest rate of radiation is to be obtained. It must suffice in the present communication to remark that nearly complete separation may occur at the surface of isolated elements of material, or if the elements of material are very small. These requirements are of interest in relation to observations of the Cassiopeia source, which show it to consist of many broken and apparently separated filaments[1].

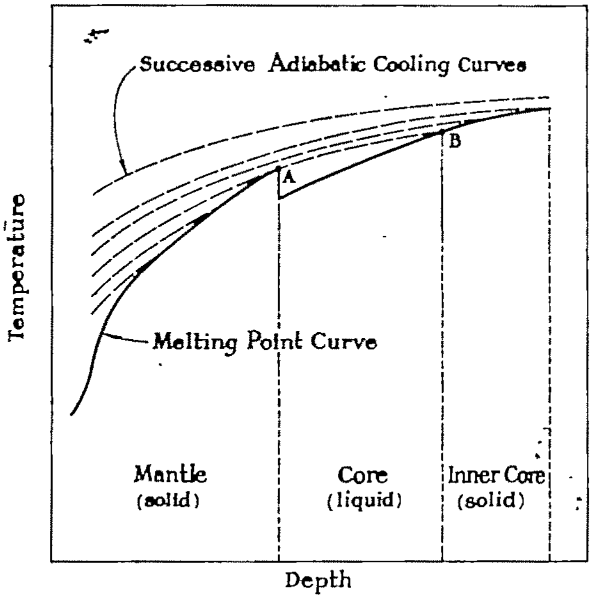
The Earth's Inner Core

All seismic work indicates that at least part of the core of the earth is liquid, since no transverse waves have ever been observed to pass through it. It has been suggested, however, that the core contains an inner core beginning at a depth of approximately 5,000 km. which is solid, although no definite proof of this has ever been given. Bullen[1], however, has shown that the rise in velocity of longitudinal waves at this depth can be explained by assuming it to be solid and of the same composition as the rest of the core. In a recent and detailed analysis of the constitution of the earth's interior, Birch[2] comes to the conclusion that the inner core is most probably crystalline iron, and the outer part liquid iron, perhaps alloyed with a small fraction of lighter elements.



Most theories of the origin of the earth agree that it passed through a molten stage before finally separating into the different layers; but no physical explanation seems to have been given as to how the inner core could have become solid. Urry[3] has shown that even an earth formed from the cold accretion of dust particles would melt by the accumulation of heat from radioactive elements, and afterwards solidify as the amount of radioactive material decreased with increasing age of the earth. Hoyle[4] has also shown that accretion should lead to a liquid planet.

Assuming the core to consist mainly of iron and the mantle of silicates, the melting-point curve is likely to be of the general shape shown in the figure. The recent work of Uffen[5] (based on seismic data and the theory of solids) has shown that the melting-point gradient in the mantle is considerably less than the theoretical curve proposed by Jeffreys[6]. At the boundary of the core and mantle there will be a discontinuity, the melting point in the iron core being less than that in the silicate mantle.

As the earth cooled from its molten state, the temperature gradient would be essentially adiabatic, there being strong convection currents and rapid cooling at the surface. Solidification would commence at that depth at which the curve representing the adiabatic temperature first intersected the curve representing the melting point temperature. It is suggested, therefore, that solidification began at the centre of the earth, and not at the boundary of the core and mantle as it is at present supposed. A solid inner core would continue to grow until a curve representing the adiabatic temperature intersected the melting-point curve twice, once at A, the boundary of the core and mantle, and again at B, as shown in the figure. As the earth cooled still further, the mantle would begin to solidify from the bottom upwards. The liquid layer between A and B would thus be trapped. The mantle would cool at a relatively rapid rate, leaving this liquid layer essentially at its original temperature, insulated above by a rapidly thickening shell of silicates and below by the already solid (iron) inner core.

No specific values of the temperatures are postulated, and the behaviour of both the adiabatic and melting-point curves is not known exactly; but if they vary qualitatively as shown, then the above argument does give a physical reason for the existence of a solid inner core.

The Rheological Curve

THE shear of a non-Newtonian body, that is, a plastic material or a high-polymeric pseudo-fluid, follows a mechanism showing analogy to that of a true fluid as expressed by the Maxwell equation; but whereas the relaxation of true fluids is purely time-dependent, in the case of non-Newtonian bodies a critical angle of tangential deformation characteristic for each material marks a threshold limit of elastic deformation before relaxation sets in. This elastic limit in plastic materials corresponds to the separation of a secondary aggregate into primary particles and, in the case of pseudo-fluids, to the inception of unkinking of the polymer molecules.

From a study of rheological data derived from non-Newtonian plastic bodies and high-polymer sols of cellulose esters, etc., we find the geometrical characteristics of the stress/shear-rate relationship to conform to a line, the curvature of which decreases with increasing velocity gradient:

$$d^2S/dv^2 = -(K)\exp(-T.v),$$

where S is the applied shearing stress, v the velocity gradient, and K and T are constants characteristic of the material.

If the very short relaxation time of the Maxwellian fluid component be considered as negligible by reason of the great magnitude of the time-scale of experimental observation, $1/T$ will be the measure of a constant rate opposing v, and a Newtonian linear relationship will be reached when the exponential term vanishes at high rates of shear. Thus, at $v = 0$, the exponential term assumes its maximum value of K/T^2.

The rheological measurements in a capillary instrument are derived solely from the stress–shear mechanism immediately contiguous to the wall-layer, and the experimental line can be expressed by the equation:

$$S = v/\mu + F_0 - (K/T^2)\exp(-T.v),$$

where $1/\mu$ is the residual or plastic viscosity measured along the asymptote, and K/T^2 is the value of the difference between the intercept to the asymptote F_0 and that of the curve on the stress axis F_1, were the regime maintained down to the value $v = 0$.

Materials of low rigidity exhibit curves which appear to have their origins at lower values of stress than is the case with materials of high rigidity. In conformity with this, the values of $(F_0 - K/T^2)$ are smaller in proportion to the Bingham intercept F_0 in the former than with the latter type.

It is probable that when the experimental line appears to cut the stress axis at a point lower than the calculated value F_1 of the curve, this is due to a progressive change in the regime to a two-dimensional planar flow ruling at very low velocity gradients, as in, for example, parallel-plate plastometry.

The value F_1 of the intercept to the curve at its origin may be determined by plotting $\ln(\Delta S)$ against the corresponding values of v, when the intercept on the ln axis gives K/T^2 and the slope of the curve gives T.

The degree of flocculation of a given material can be assessed by the value of the integrated area K/T^2.

Oceanic Duct and its Effect on Microwave Propagation

THE formation of a microwave duct over the sea has been examined in terms of a distribution of potential refractive index (refractive index independent of height in an adiabatic atmosphere) corresponding to a functional relationship originally suggested by Deacon[1] to describe the distribution of certain meteorological properties in the boundary layer. Deacon's relationship takes the stability of the atmosphere into account in terms of a profile index, β, which is a function of air–sea temperature difference and wind velocity.

The resulting profiles of potential refractive index are then related to the trapping of microwaves by

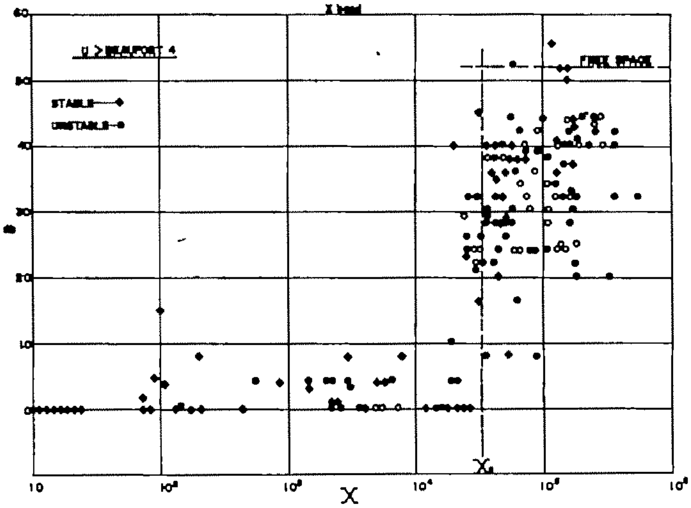

Fig. 1. Field-strength in db. above 1 microvolt/metre, vs. X, X-band, wind > 15 m.p.h.

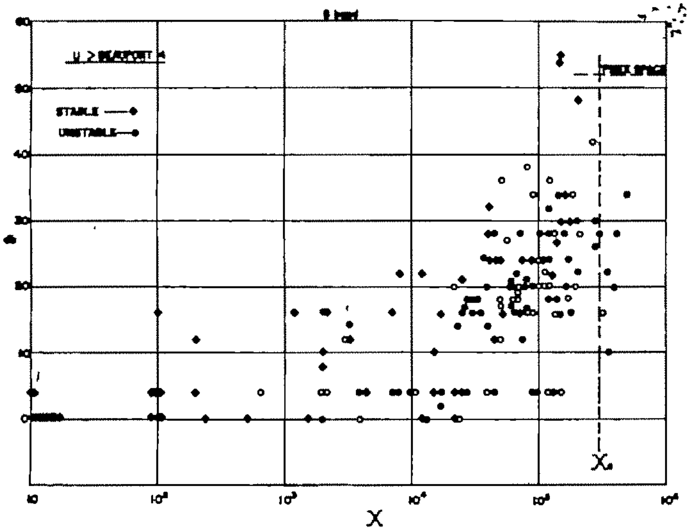

Fig. 2. Field-strength, vs. X, S-band, wind > 15 m.p.h.

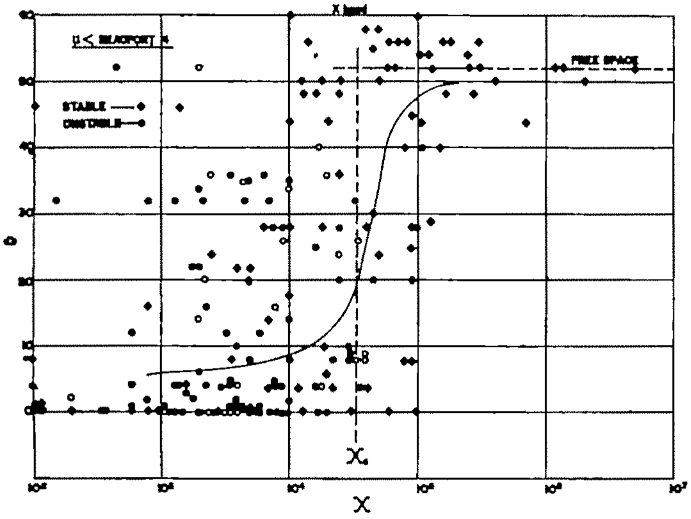

Fig. 3. Field-strength, vs. X, X-band, wind < 15 m.p.h.

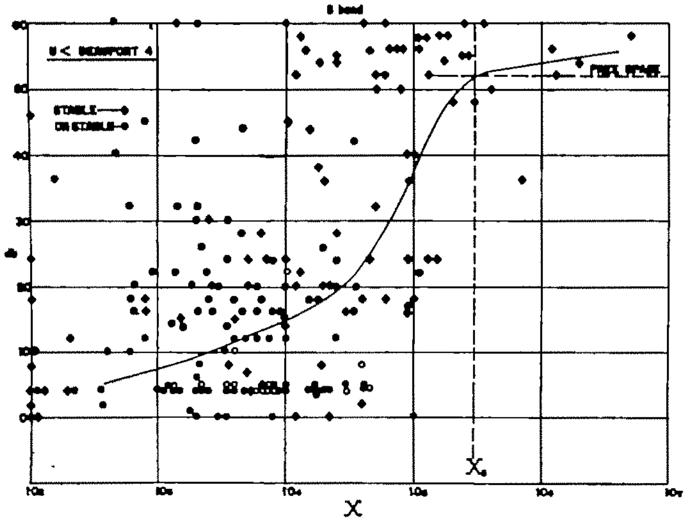

Fig. 4. Field-strength, vs. X, S-band, wind < 15 m.p.h.

use of a technique due to Schelkunoff[3], in which a given profile is replaced by two layers each of constant modified refractive index in such a way that distributions of radio field-strength are virtually unchanged.

These operations lead to a criterion for trapping in terms of meteorological parameters. Calling this criterion X, we obtain :

$$X = \left[\frac{(3-\beta)(\beta-1)}{0\cdot06\ (2-\beta)}\left(\frac{(n_1-n_0+h_1/5R)\times10^6}{h_1^{1-\beta}-z_0^{1-\beta}}\right)\right]^{3/\beta}\frac{\beta}{3-\beta}$$

where n_1 and n_0 are index of refraction at h_1 and sea surface respectively ; β is profile index of the potential refractive index distribution ; h_1 is height at which meteorological measurements are taken ; z_0 is a parameter of surface roughness ; and R is radius of the earth.

When X exceeds 3,770 λ^2 (where λ is the wave-length in cm.), trapping should occur.

Results obtained at Cardigan Bay in the Irish Sea were kindly loaned to us by Dr. J. S. McPetrie and were analysed in terms of the criterion indicated above. Since the antenna heights were 97 ft. (much too high to take full advantage of the oceanic duct) considerable scatter is to be expected. However, it was hoped that the results would be adequate to determine whether the effects of stability could explain two aspects of the Cardigan Bay data about which considerable discussion has arisen. These are : (1) the fact noted by Jones[3] that high signals are usually associated with high wind speeds when negative air–sea temperature differences are present ; (2) the tendency noted by McPetrie and Starnecki[4] for high signals to be associated with large positive air–sea temperature differences.

It is believed that the present model adequately explains both of these points in terms of the manner in which Deacon found the parameter, β, to vary with stability. Thus, it is seen that : (1) Figs. 1 and 3 show that a far higher percentage of the unstable cases exceed the critical when high winds are observed than when low winds are present ; (2) Figs. 3 and 4 (the cases when wind velocities are low and stability is thus relatively more important) show that relatively many more stable (positive air–sea temperature difference) than unstable cases give a X which exceeds the critical value required for trapping. While the cases of low wind velocity show a great deal of scatter, this tendency seems rather definite.

These two features, coupled with the good agreement between observation and theory shown by Figs. 1 and 2, strongly indicate that the suggested model, which takes atmospheric stability into account, properly describes the processes involved.

The large scatter at low wind velocities is probably due to a variety of causes such as summer-time subsidence inversions, path inhomogeneities, and, perhaps most important, the extrapolation of meteorological readings taken over land to over water conditions when winds are very light. On the whole, however, the median lines show that the tendency so definite in Fig. 1 is still present in Figs. 3 and 4 though obscured by some other factor or factors. The predicted break in X is generally sharper on the X-band than on the S-band, as might be expected, and appears to occur much nearer its theoretical value. On the other hand, the S-band appears to break sooner than anticipated, and to 'feel' the duct some time before it is actually trapped.

Interaction between Crystal Slip and Grain Boundary Movement

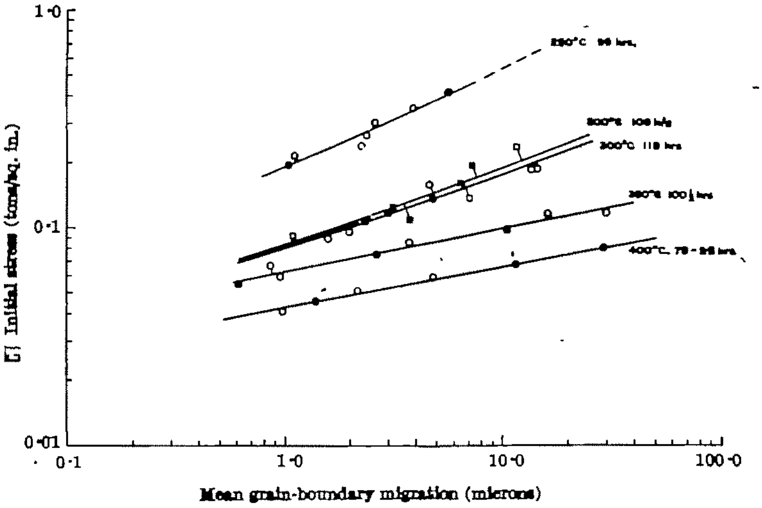
SEVERAL workers have shown that when polycrystalline metals are made to creep, that is, to deform at an elevated temperature, the grain boundaries move in a direction more or less perpendicular to themselves, just as when grain growth occurs[1]. This is migration of the boundaries, as distinct from the sliding movement, which also occurs during creep, of one grain past another. Some recent measurements show that the amount of movement is a function of the applied stress. An explanation of this is put forward here which involves an interaction between crystal slip and movement at boundaries.

Aluminium specimens were allowed to creep at (longitudinal tensile) stresses ranging between 1/20 ton and ½ ton/sq. in. at temperatures of 250°, 300°, 350° and 400° C., in all cases for approximately a hundred hours, and the average distance through which the grain boundaries migrated was measured. The results are plotted against applied stress for each temperature in the graph. At any of these temperatures the amount of migration depended very sensitively on the magnitude of the applied stress. The sensitivity was, in fact, large enough to be quite obvious from simple micro-examination. It seems fair to conclude that virtually all the migration was caused by the applied stress, and that the amount due to surface-tension forces, which is another possible cause, was negligible.

The following situation must develop at a boundary during deformation. Dislocations approaching the boundary will experience a force tending to halt them. The boundaries will experience the equivalent opposite force. At high enough temperatures the boundaries are mobile and should move under the stimulus of the applied force, although at low temperatures when they are immobile, dislocations will be stopped unless the applied stress is large enough to force them through the boundaries. The average pressure on the boundary can easily be estimated. The force on 1 cm. length of dislocation due to an applied stress σ is σb, where b is the Burgers vector of the dislocation. If a section through the boundary shows n dislocations held up by 1 cm. of it, the average pressure on the boundary is $n\sigma b$. As the applied stress σ is increased, the number of dislocations n will in all probability increase considerably, so that the average pressure on the boundary will increase on two counts. This could explain the rather strong dependence shown in the graph of the distance migrated on the applied stress. The remarks in this paragraph are independent of any special model of a boundary, such as the dislocation model[2] or the island model[3]. The details of the model would be important, however, in calculating the rate of migration.

At this point there may seem to be a contradictory state of affairs. The stress around an edge dislocation is not uniform. On the upper side of a positive edge dislocation the stress is compressive, on the lower side tensile; and it might at first sight seem that this contradicts the idea of a 'pressure' on the grain boundary. The explanation is that the non-uniform pressure and tension act on the individual *atoms* in the boundary, but the overall pressure acts on the *arrangement* of atoms which constitutes the boundary. This distinction coincides with the fact that when the boundary moves a relatively long distance, individual atoms move only a fraction of an interatomic spacing. The situation is analogous to that occurring with a dislocation itself; when a stress is applied, for example, to a positive edge dislocation, the atoms on the upper side and those on the lower side move only a fraction of an interatomic spacing in opposite directions; but the arrangement of atoms constituting the dislocation may move a relatively large distance and be capable of overcoming obstacles, and may therefore be said to experience a force impelling it forward.

The boundary should show some of the properties of dislocations. Thus, if particles of precipitate occur along it and reduce the interfacial energy, it will tend to anchor to these particles. If it is stabilized



by segregation to it of solute atoms, migration will be hindered if the rate of diffusion of the solute atoms is low, just as with an 'atmosphere' around a dislocation.

Score Resistance of Bearing Metals

Score resistance is the property of a bearing that enables it to resist welding to its journal. Although it is a property of the greatest technical importance, knowledge of score resistance has for many years been largely empirical, and efforts to relate score resistance to other more readily definable properties have met with only limited success.

In studying the performance of a large number of bearing metals, we have found that the good bearing metals are those which at their melting points have extremely limited solid solubilities in iron. Thus, lead, tin, indium, thallium and cadmium have excellent score resistance and negligible solubility in iron. Copper, gold, platinum and nickel, on the other hand, have poor score resistance and large solubility in iron. Silver, zinc and aluminium are intermediate as regards both score resistance and solubility in iron. The more dissimilar two metals are, the greater will be their score resistance when rubbed together. Specifically, the metals should be dissimilar with regard to, first, crystal binding forces and, secondly, atomic sizes. The former factor is most readily described in terms of the periodic classification of elements, as was pointed out by Underwood[1]. Thus, the main journal metals (iron, nickel, chromium, manganese, vanadium and molybdenum) are all transition metals with strongly metallic binding. These, as well as metals (such as copper and gold) which immediately follow transition groups in the periodic classification, have poor score resistance when used as bearing metals in conjunction with steel journals. The *B*-subgroup metals (such as lead, tin, indium, cadmium and thallium), which have less strongly metallic binding, have been found to have excellent score resistance when run against transition metal journals. Exceptional cases are silver and zinc. Silver is a metal which occurs immediately after a transition group but which has unfavourable atomic size for alloying with iron (as defined by Hume-Rothery[2]) and technically acceptable score resistance when run against steel. Zinc is two atomic numbers removed from a transition group but has a favourable atomic size and is an undesirable constituent of bearing metals.

The essentially non-metallic binding of inter-metallic compounds indicates that such materials should have good score resistance, regardless of the score resistance of their constituents, and this has been borne out by our experiments.

The above factors provide an explanation for the anti-score characteristics conferred upon metal surfaces by films of compounds such as oxides, chlorides, sulphides, selenides and the like.

A more complete account of these and other aspects of score resistance will be published elsewhere.

Hydrolysis of Organic Nitrites

In continuation of investigations into the mechanisms of reactions of organic esters[1], a study has been made of the hydrolysis of some simple organic nitrites. It was known[2] that the acid-catalysed hydrolysis of these esters is very rapid at room temperature, while the rate of reaction in alkaline media is comparatively slow.

Acid catalysis. The hydrolysis of *n*-propyl, *tert.*-butyl and benzhydryl nitrites has been studied at 0° C. in 72·5 per cent dioxan-water (by weight) as solvent in the presence of small concentrations of mineral acids. Kinetics observed were of the first order with respect to the nitrite concentration, and with perchloric acid as the catalyst the first-order constants are directly proportional to the acid concentration over the range 0·001–0·007 *M*, wherein the reaction proceeds at a convenient speed. For a fixed hydrogen ion concentration, and at constant ionic strength, a further marked catalysis was observed on addition of chloride and bromide ions, the increase in rate being proportional to the halide concentration up to 0·012 *M*. The results may be interpreted as follows:

$$RONO + H^+ \xleftrightarrow{\text{fast}} (RONOH)^+$$

$$(RONOH)^+ + H_2O \xleftrightarrow{\text{slow}} ROH + (H_2ONO)^+$$

$$(RONOH)^+ + X^- \xleftrightarrow{\text{slow}} ROH + NOX \; (X = \text{Cl, Br}).$$

Omitting the concentration of water, since this is in large excess, the expression for the rate becomes:

$$\frac{-d(RONO)}{dt} = k_1(H^+)(RONO) + k_2(H^+)(RONO)(X^-).$$

Values of k_1 and k_2 are:

	k_1 (sec.$^{-1}$ gm. mol.$^{-1}$ l.)	k_2 (for X = Br) (sec.$^{-1}$ gm. mol.$^{-2}$ l.^{2})
n-Propyl nitrite	0·218	26·8
tert.-Butyl nitrite	0·526	8·9
Benzhydryl nitrite	0·19	27

Alkaline catalysis. The hydrolysis of *n*-propyl and *tert.*-butyl nitrites by sodium hydroxide in 60 per cent dioxan-water has been studied over the temperature range 25–55° C. Good second-order kinetics were observed, and the rate constants are found to be in accordance with the usual relationship:

$$\log_{10} k_2 = \log_{10} A - \frac{E}{2 \cdot 303\, RT}.$$

The following values of $\log_{10} A$ and E were calculated, the units of A being sec.$^{-1}$ gm. mol.$^{-1}$ litres :

	k_2 (35°)	E (k.cal.)	$\log_{10} A$
n-Propyl	$7 \cdot 6 \times 10^{-6}$	17·5	8·31
tert.-Butyl	$13 \cdot 2 \times 10^{-7}$	20·5	8·75

The neutral solvolytic reaction under these conditions is very slow, the rate coefficient for *n*-propyl nitrite, for example, being not greater than $1 \cdot 5 \times 10^{-8}$ sec.$^{-1}$ at 35° C.

Position of bond fission. It is known[3] that the pyrolysis of alkyl nitrites occurs by the fission of the nitrosyl oxygen bond, RO—|—NO. The ester exchange reaction between *l*.-2-octyl nitrite and *sec*.-butyl alcohol has been found[4] to produce optically pure *l*.-2-octyl alcohol. In the present work complete retention of configuration has also been observed for the esterification of *l*.-2-octyl alcohol with nitrous acid in water, and for the subsequent hydrolysis of the ester in dilute acid and in alkaline media. Thus it is evident that, for this ester, the nitrosyl–oxygen bond alone is broken over the whole range from dilute acid to dilute alkaline conditions.

Experiments in which *n*-propyl and *tert*.-butyl nitrites were dissolved in their respective alcohols, sealed, and kept at 35° C. for many weeks, showed complete absence of the formation of ether which would have resulted from any small percentage of alkyl–oxygen bond fission.

The absence of carbonium ion formation in the acid-catalysed hydrolysis of *tert*.-butyl nitrite under kinetic conditions has been shown by the complete absence of any formation of olefin, and also by experiments in the presence of water enriched with $H_2{}^{18}O$. At the end of the reaction, the *tert*.-butyl alcohol isolated was found to be of normal isotopic composition.

Within the range of structural and environmental conditions examined, it is probable that the rate-determining stage consists of the attack of a nucleophilic reagent on the nitrogen atom of the ester (alkaline hydrolysis) or of the protonated ester (acid hydrolysis) ; but we cannot exclude the possibility of other mechanisms under other conditions, particularly one which is related to the mechanism now put forward, as S_N1 is related to S_N2. Further investigations are in progress with other organic nitrites under various conditions.

A full account of this work will be published elsewhere. Acknowledgment is made to Prof. E. D. Hughes and Prof. C. K. Ingold for advice and encouragement, and to Drs. C. A. Bunton and D. R. Llewellyn for their collaboration in the experiments with isotopically enriched water. Much of this work was made possible by the provision of a maintenance grant by the Ministry of Education.

Deoxyribonucleic Acid Content of the Germinal Vesicle of the Ovocyte in *Fasciola hepatica*

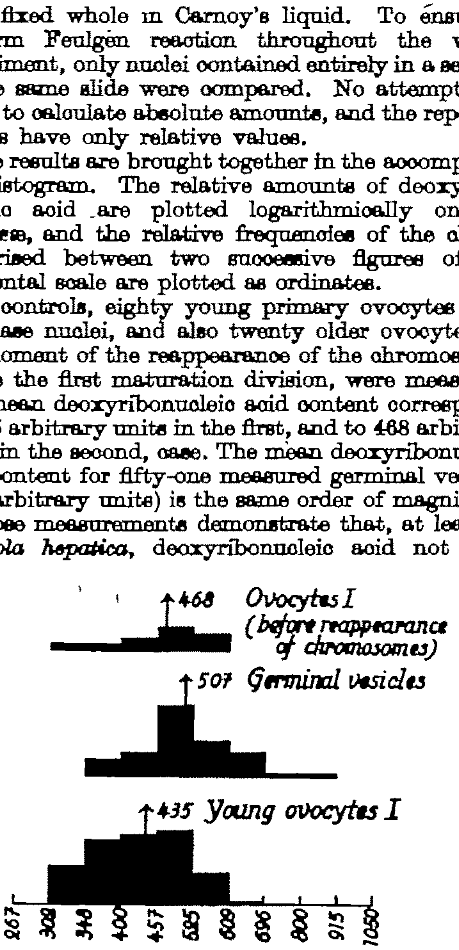
SINCE deoxyribonucleoproteins possibly constitute a substratum of the genome, the problem of the permanent character of deoxyribonucleic acid in the cell nucleus is of much present interest, and especially in the elements of the germinal lineage. However, it is known that in the nucleus of the primary ovocyte, after it swells to form a germinal vesicle, Feulgen's reaction becomes negative, or in some species very slightly positive. J. Brachet[1] demonstrated by means of centrifugation that, even in the cases of negative Feulgen's reactions, deoxyribonucleic acid is present in the germinal vesicle, but too dilute to give a visible re-coloration of the fuchsin : after centrifugation, a centrifugal cap of the acid was detected even in cases of negative reaction. The permanent character of the deoxyribonucleic acid was also qualitatively demonstrated in the germinal vesicle ; but the quantitative aspect of the problem remains, so far as we know, still an open question.

In *Fasciola hepatica*, the germinal vesicle contains a nucleolus surrounded by 'nucleolar associated chromatin' and a network of extremely thin Feulgen-positive filaments. Their distribution is homogeneous enough to permit quantitative valuations of the deoxyribonucleic acid content by means of the histophotometrical method of L. Lison[2]. The animals were fixed whole in Carnoy's liquid. To ensure a uniform Feulgen reaction throughout the whole experiment, only nuclei contained entirely in a section of the same slide were compared. No attempt was made to calculate absolute amounts, and the reported figures have only relative values.

The results are brought together in the accompanying histogram. The relative amounts of deoxyribonucleic acid are plotted logarithmically on the abscissa, and the relative frequencies of the classes comprised between two successive figures of the horizontal scale are plotted as ordinates.

As controls, eighty young primary ovocytes with prophase nuclei, and also twenty older ovocytes, at the moment of the reappearance of the chromosomes before the first maturation division, were measured. The mean deoxyribonucleic acid content corresponds to 435 arbitrary units in the first, and to 468 arbitrary units in the second, case. The mean deoxyribonucleic acid content for fifty-one measured germinal vesicles (507 arbitrary units) is the same order of magnitude.

Those measurements demonstrate that, at least in *Fasciola hepatica*, deoxyribonucleic acid not only



persists, but also remains quantitatively constant in the germinal vesicle.

This investigation was aided by a grant from the Belgian National Foundation for Scientific Research.

Complex Reactions of Cytochrome *c*

During measurements of the time course of reduction of the cytochrome system of living wheat roots (cf. ref. 1), it was observed that the γ-band at λ 418 of *c* develops considerably slower than the corresponding α-band at λ 550 mμ. The wheat roots are provided with a complete cytochrome system, the prosthetic groups of which correspond to the cytochromes *a* (cytochrome oxidase), *c* and *b*. Before *b*, a fourth component, probably identical with succinic dehydrogenase, acts as the source of electrons. This component has a strong band at 570–575 mμ.

At normal aeration the cytochromes maintain a high degree of oxidation, amounting to 64–84 per cent of the total quantities. With cessation of oxygen supply the steady states are moved in direction of complete reduction. Because the root tissue holds certain quantities of oxygen, this process proceeds gradually in a few minutes, the time course thus enabling a fairly accurate recording of the single bands. It was now observed that the increase of the Soret bands and α-bands of *a* and *b* run approximately synchronously. Averages of six readings resulted in a half time (= from aerobic oxidation to 50 per cent remaining reduction) of 266 sec. for *b*γ (λ 427 mμ), and 272 sec. for *b*α (λ 562 mμ). Because the reduction of the cytochrome oxidase runs considerably faster than that of *b* (see ref. 2) no accurate values are hitherto available concerning this cytochrome. But the time curves show no pronounced discrepancies between *a*γ and *a*α. As to cytochrome *c*, however, the development of the reduced Soret band shows a great lag of time as compared with the α-band. An average of six series rendered the half-time values 250 sec. for the Soret band but only 65 sec. for *c*α.

The results point to the interference of a complex reaction between cytochrome *c* and a substrate. Because the spectrograms of *a* and *b* do not reveal a corresponding disturbance, it seems unlikely to surmise compounds between the cytochromes themselves. The idea of an intermediate catalyst between *c* and *b* has now been presented by Slater[3], and it may be tentatively assumed that such an intermediate factor serves as the substrate of oxidized cytochrome *c*, resulting in a complex $c_{\text{ox}} \times \textit{factor}_{\text{red}}$. This complex undergoes oxido-reduction to $c_{\text{red}} \times \textit{factor}_{\text{ox}}$. Dissociation of the complex is brought about either by oxidation of c_{red} by cytochrome oxidase, or by reduction of $\textit{factor}_{\text{ox}}$ by cytochrome *b*. The scheme explains why so little of the complex is noticed at normally working aerobic respiration. At inhibited cytochrome oxidase a comparatively large quantity of the complex will be immediately formed and, at increasing anaerobiosis, slowly decomposed by *b* and the dehydrogenase, synchronously with the reduction of both *c* and the factor. Work is in progress bearing on the calculation of the equilibrium constants.

The strong depression of the Soret band of cytochrome *c* in the complex reaction is reminiscent of the enzyme-substrate compounds of peroxidase[4].

Attention is directed to the fact that the hæmatin of cytochrome *c* is closely related to that of peroxidase.

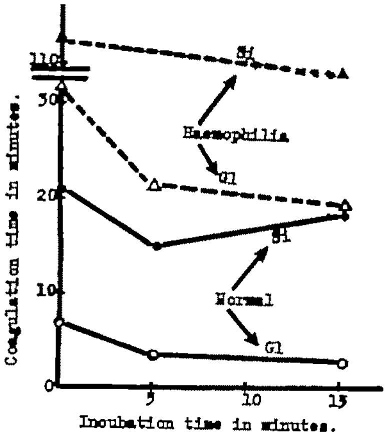
Formation of Thromboplastin in Shed Mammalian Blood

A number of substances are available to maintain the fluidity of blood outside the organism. It is usually assumed that the addition of the anti-coagulants does not produce any change of the blood components involved in the clotting process. However, if after the addition of adequate quantities of citrate to blood, the cellular elements are removed and the calcium ion concentration is re-established in the separated plasma, then coagulation of the plasma will occur generally in a far shorter time than in blood which is allowed to clot without interference. It appears that some activation occurs during the isolation procedure.

In order to obtain information on this activation process, it was thought desirable to carry out experiments with whole blood, and thus obviate influences due to change in the cellular composition, and to handling. Venous blood was collected from humans, first with glass and then with silicone-coated syringes. ('Silicone Dri Film 9987', General Electric, was used.) Measured volumes of blood were distributed into both glass and silicone-coated coagulation tubes, maintained at 37° C. The arrangement was as follows: (*a*) Whole blood coagulation time was determined in 1·5-ml. aliquots. (*b*) In a further series, the tubes contained 0·55 ml. of 0·15 *M* sodium chloride solution to which 1 ml. blood was added. (*c*) In a third series, 1 ml. blood was added to 0·55 ml. of a solution containing 0·037 *M* tri-sodium citrate, 0·06 *M* sodium chloride and 0·046 *M* calcium chloride. (*d*) 1 ml. blood was added to 0·4 ml. of a solution containing 0·051 *M* tri-sodium citrate, and 0·082 *M* sodium chloride. This series was incubated for varying times before 0·15 ml. of 0·16 *M* calcium chloride was added. The setting up of the four series required approximately one minute. The experiments were carried out with blood specimens taken from eleven normal human donors, and from six hæmophiliacs.

A summary of the results of the experiments is given in the accompanying graph.

From these results it is apparent that normal human blood incubated with sodium citrate in glass tubes (curve Normal *Gl*) for periods up to 15 min. clots on recalcification in an average time of 2·5 min. (varying from 1·5 to 3·5 min.), which compared with the starting value of 7 min. (varying from 4 to 10



Coagulation-time of whole blood after incubation with sodium citrate in wettable or water-repellent tubes

min.) represents a considerable acceleration. On the other hand, treatment of normal blood in contact with a siliconized tube (curve Normal Si) showed an initial drop of the coagulation time[1], but little further change occurred during the incubation period. Blood from hæmophiliacs behaved less uniformly than normal blood. According to the type of deficiency, incubation in glass resulted in either shortening or no change in clotting time, while when in contact with a siliconized surface in no case was a difference between start and end values observed. The significance of these observations will be discussed more fully elsewhere.

Since several workers connect the thrombocytes with the supply and activation of clotting components, thrombocyte counts[2] were carried out simultaneously with coagulation experiments.

Statistical evaluation of the counts indicated that incubation of citrated blood at 37° C. for 15 min. did not produce a significant change in the number of thrombocytes ($t = 0 \cdot 75$, d.f. $= 38$; for $P = 0 \cdot 01$, $t = 2 \cdot 58$). Regarding other means of maintaining fluidity of the shed blood, it appears that application of cation exchange resins to remove calcium ions does not prevent acceleration of coagulation because of the surface properties of the resins. The addition of heparin to blood in contact with 'Pyrex' glass was also found to be of limited value, despite the fact that adequate amounts of heparin were added. Addition of salmine sulphate to abolish the heparin effect resulted in shortening of the coagulation time of whole blood. Finally, addition of ethylene diamino-tetra-acetate to whole blood in 'Pyrex' glass to give a concentration of 0·2–0·5 per cent resulted in a marked delay of the coagulation time following the addition of excess calcium ions. This apparently strong antithrombin effect of diamine-tetra-acetate[3,4] masks other reactions. If it is desired to obtain unmodified blood with regard to the clotting factors, it is necessary to collect blood in containers with surface properties similar to that of the silicones. The addition of citrate or oxalate is permissible.

The results reported are consistent with the assumption that normal blood plasma contains a soluble precursor of the thromboplastin complex[5,6,7], which in contact with glass at calcium ion concentration as low as 10^{-4} *M* becomes activated. This seems to be the first step in the chain of the clotting process. No breakdown of platelets occurs during that phase. It is very likely that the glass surface acts as a kinase activating the precursor prothromboplastin to thromboplastin.

Anti-Diuretic Substances of the Blood

The intraperitoneal injection of either human serum or plasma (0·5–1 ml. per 100 gm. of body-weight) inhibits urinary excretion of hyperhydrated rats. This effect disappears when either serum or plasma is dialysed against running water for 12–24 hr. Incubation at 37° C. during a period longer than eight hours destroys practically all the anti-diuretic potency of serum provided that bacterial contamination is avoided[1].

The blood serum of pregnant women shows a progressive anti-diuretase enzymatic activity, that is, the power to destroy the pressor and anti-diuretic effect of vasopressin when the latter is added. During the ninth month of pregnancy, 0·1 ml. of serum destroys from 300–350 mU. of vasopressin in a period of 40–50 min. This is rather surprising since it has been calculated that the hypophysis liberates an amount of anti-diuretic hormone equivalent to 1–5 mU. per hr.[2]. The serum obtained from a pregnant woman and injected into the rat (Burn's test[3]) has, however, greater anti-diuretic potency than serum from a non-pregnant woman (Fig. 1). Dialysis performed in a cellulose tube decreases similarly the anti-diuretic potency of serum from pregnant and non-pregnant women. Incubation at 37° C. of serum obtained during pregnancy inactivates its anti-diuretic substances; but the inactivation follows a time course which is similar for pregnant and non-pregnant women, in spite of the fact that the former has greater anti-diuretase activity (Fig. 1).

It seems evident that the presence of vasopressin would not explain by itself the anti-diuretic effect of serum. Apparently enteramine[4] may be disregarded because neither dibenamine nor dihydroocornine neutralizes the anti-diuretic action of serum when injected in rats (Burn's test).

In five patients suffering from diabetes insipidus, it has been possible to demonstrate that the anti-diuretic potency of their serum is no different from serum of normal individuals[5]. In this case Burn's test was also used.

Careful analysis of these results indicates that the anti-diuretic effect of serum, evaluated by the Burn's test, may be caused by the action of two substances present in the serum: (*A*) free anti-diuretic hormone,

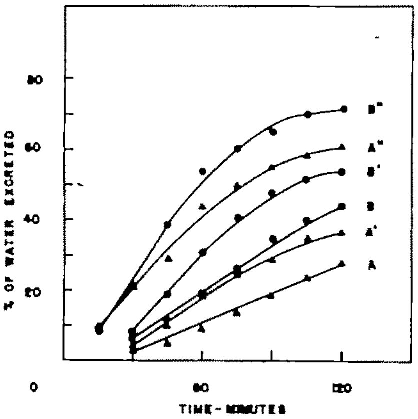

Fig. 1. Each curve represents the percentage of urinary excretion of 80 hyperhydrated rats (Burn's test). The following intraperitoneal injections expressed in 100 gm. of body weight were given:

A, 0·5 ml. of serum obtained from women in the ninth month of pregnancy, kept at – 5° C. up to moment of the injection; samples of 20 women.

B, 0·5 ml. of serum obtained from non-pregnant women and also kept at – 5° C.; samples of 20 women.

A', as *A*; sera incubated at 37° C. during 4 hr.

B' as *B*; sera incubated at 37° C. during 4 hr.

A", as *A*; sera incubated during 8 hr.

B", as *B*; sera incubated during 8 hr.

probably vasopressin; and (*B*) a substance similar to the latter which may be loosely linked to a protein and which would have no physiological effect unless liberated from this protein. Substance *A* would be present in small quantities in the blood and would be easily destroyed by anti-diuretase enzyme; therefore, its action would disappear rapidly from the serum of pregnant women. Substance *B* would be protected from enzymatic activity while linked to a protein; after prolonged dialysis of serum it would be liberated and thus eliminated. Serum probably contains a larger proportion of substance *B* than substance *A*.

When the Burn's test is carried out, the rat shows the effect of substances *A* and *B*. The latter is inactive in the donor's blood while linked to the protein; it is liberated and then activated as soon as it is injected into the peritoneum of the recipient rat. Because substance *A* is present in very small quantities, and furthermore is rapidly vulnerable to enzymatic action, the intensity of the anti-diuretic effect is mainly due to substance *B*.

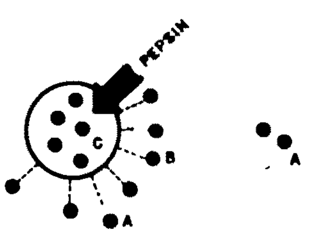

Fig. 2. Distribution of anti-diuretic substances in serum.

A: less abundant than *B* and *C* even in normal subjects, represents the free and active fraction, that is, the anti-diuretic hormone (vasopressin ?); easily inactivated by enzymes (antidiuretase) and dialyses rapidly.

B: This fraction and *C* are linked with proteins, and present in the blood in larger quantities than *A*. Inactive while linked. *B* is loosely linked and easily liberated and transformed in the active hormone.

C: This fraction is strongly linked to proteins. It is not liberated by dialysis or inactivated after incubation of serum (37°). It is liberated only after deep hydrolysis of proteins (peptic digestion, pH 2·5–3·5). The circle represents the molecule of protein; the arrow the destruction of this molecule, which allows the liberation of fraction *C*

When serum has been dialysed, it loses its anti-diuretic effects and it has neither *A* nor *B* factors; nevertheless, by adequate treatment with pepsin (pH 2·5–3·5) it liberates a peptide which has similar properties to vasopressin[6]. This forms another fraction (fraction *C*) which, like fraction *B*, is linked to a protein; but in order to liberate it, great disintegration of the protein molecule is necessary. The anti-diuretic effects of fraction *C*, which resembles vasopressin, are not inhibited either by dibenamine or dehydroergocornine. The probable distribution of these fractions is summarized in Fig. 2.

Enzymatic Hydrolysis of Xylan

A PREVIOUS investigation[1] has shown that enzymes from *Chaetomium globosum* are able to hydrolyse wheat straw xylan to xylose with the formation of a series of intermediates, designated *a*,*b*,*c*, . . . *g*, which appear on paper-chromatograms with regularly decreasing R_F-values, and which are believed to be oligosaccharides with regularly increasing xylose units: xylobiose[2], xylotriose, xylotetraose . . . etc. By heating or storing the enzyme preparations, it was possible to arrest the hydrolysis at the xylobiose stage, indicating that two enzymes are present, (*A*) hydrolysing the xyloside chain to xylobiose and (*B*) hydrolysing xylobiose to xylose.

The investigation has been continued with a *Streptomyces* sp. and a *Micromonospora* sp. isolated from compost, a *Cellvibrio* sp. isolated from soil by Dr. H. L. Jensen, and *Chaetomium globosum*. The organisms were grown on media containing 0·5 per cent xylan in a colloidal solution as source of carbon. Culture filtrate and acetone-dried cell material were used as enzyme sources.

Intermediates. Determinations of constituent sugars in intermediates were carried out by paper-chromatography (three different solvents, development for 40 hr.) after acid hydrolysis of the intermediates extracted from paper sheets[3]. From the accompanying table it is seen that intermediate *a* and *b* yielded xylose only. In intermediate *a* the ratio of reducing sugar[4] after and before hydrolysis was found to be approximately 2, indicating the disaccharide xylobiose[2]. The same ratio for *b* was found a little less than the theoretical value for a trisaccharide (probably because of the small amounts subjected to acid hydrolysis and sugar determinations); but enzymatic hydrolysis (see below) of *b* yielded xylose and xylobiose in equal concentrations, and it is concluded that *b* is xylotriose[2].

SUGARS FOUND AFTER ACID HYDROLYSIS OF INTERMEDIATES RESULTING FROM ENZYMATIC HYDROLYSIS OF XYLAN OR MILD ACID HYDROLYSIS OF WHEAT STRAW

Intermediates	R_F*	Hydrolysates enzymatic	acid	Constituent sugars†
a	1·0	+	+	Xylose
I	0·84	+	−	Xylose, arabinose
II	0·77	−	+	Xylose, arabinose, galactose, (glucose)
III	0·60	−	+	Xylose, glucose, galactose, (arabinose)
b	0·38	+	+	Xylose

* In relation to *a* (xylobiose), for the solvent ethyl acetate : acetic acid : water, 9 : 2 : 2.

† Brackets indicate that the sugar is found only in traces.

Three faint spots indicating other intermediates were situated between xylobiose and xylotriose; the R_F values and constituent sugars found after extraction and acid hydrolysis are given in the table. These intermediates may originate from the polyuronide part of the xylan. During the enzymatic hydrolysis of a colloidal solution of xylan, an enzyme-resistant precipitate appeared which, after isolation and acid hydrolysis, yielded the following sugar units: xylose, arabinose, mannose, glucose, galactose, uronic acid, and a trace of rhamnose. This precipitate may represent the polyuronide part of the xylan. In the culture filtrate after growth of the organisms on media containing 0·5 per cent colloidal xylan and in the acid hydrolysate from wheat straw (see below), one or several compounds were found of which the barium salt is soluble in water but insoluble in ethanol and ether, and which after acid hydrolysis yielded the same sugars as the 'polyuronide precipitate'. Judging from the intensity of the spots on the chromatograms, the sugars were present in approximately the same concentrations, except that the barium salt of the acid hydrolysate contained very little arabinose.

Mild acid hydrolysis of powdered ether- and ethanol-extracted wheat straw yielded almost the same sugars and intermediates as found after enzymatic hydrolysis of xylan (see table). Arabinose seemed to be the first product to appear; glucose was found only in very small amounts, but galactose in somewhat larger quantities.

Culture filtrate of the *Streptomyces* sp., added to powdered and extracted wheat straw, was able to split off from the wheat straw the following sugars: xylose, arabinose, glucose, xylobiose, xylotriose and other intermediates.

Enzymatic hydrolysis of xylobiose and xylotriose. Culture filtrates or powdered acetone-dried cell material were added to the sugars prepared by extraction from paper sheets[3]. In some cases the reaction products were determined quantitatively.

Culture filtrates of *Chaetomium globosum*, *Streptomyces* and *Micromonospora* were able to split xylotriose to equal amounts of xylose and xylobiose, but unable to split xylobiose to xylose, whereas the cell materials effected the hydrolysis of xylobiose to xylose. These results indicate that at least two enzymes are active in the hydrolysis of xylan—an exoenzyme (*A*) able to act on xyloside chains with three or more xylose units, and an endoenzyme (*B*) which is able to split xylobiose. Consequently, the specificity appears to depend on something related to molecule-size or chain-length of the substrate.

Culture filtrates and cell material of the *Cellvibrio* sp. were both able to split xylotriose and xylobiose to xylose; but it is not yet known if only one enzyme is present in this organism, or if both enzymes are excreted into the medium.

A more detailed account will appear later.

Carcinogens and Oxidized Fatty Acids in the Skin

Rusch and Kline[1] showed that carcinogenic hydrocarbons inhibit the autoxidation of unsaturated fatty acids. Thiobarbituric acid is a reagent for the estimation of fatty acid peroxides[2,3] and has been used for confirming the inhibition of the autoxidation of fatty acids, in particular linolenic acid, by these compounds. Pieces of excised skin placed in thiobarbituric acid give the characteristic red colour produced by the reaction of this acid with oxidized fatty acids[3]. Various carcinogens were painted on the skin of white mice to determine their effect on the peroxide concentration *in vivo*. Previous experiments have shown that the carcinogens inhibited the peroxide formation in homogenates of brain and skin. The compounds themselves do not interfere with the thiobarbituric acid reaction.

The hair was clipped from both flanks, and care was taken not to injure the epidermis. To one flank, one of the following compounds was applied: 3,4 benzpyrene, 20-methyl cholanthrene, and chrysene in a concentration of 0·3 per cent in benzene, 2-aminofluorene and 2-nitrofluorene in a concentration of 2 per cent in acetone. To the other flank, the solvent alone was applied. The mice were killed at intervals, equal areas of skin excised, and placed in 0·75 per cent thiobarbituric acid at room temperature. The development of colour was estimated qualitatively at intervals for a period of 3–4 hr.

If the mice were killed immediately after the application, there was a slight decrease in intensity of colour over that of the control side. This became more striking when the mice were killed 24 hr. after application. The difference was less after 48 hr. and was negligible after 72 hr. The effect was seen only on the epidermal side; that is, the colour which developed in the subcutaneous fat was not affected by any of the compounds. The yellow colour of the fluorenes interfered only slightly with the qualitative estimation of the thiobarbituric acid colour. Several daily applications of the compounds before killing the animals did not increase the differences in the 24-hr. values.

Five carcinogens were found to inhibit colour development to approximately the same extent. (Stilbœstrol, used as a control, had no effect.) Since they differ markedly in their carcinogenic activity[4], the inhibition they produce in fatty acid oxidation may be a necessary, but certainly is not a sufficient, condition for tumour production. It may be pointed out that oxidized fatty acids are more effective inhibitors of certain enzymes[5] and of bacterial growth[6] than the corresponding unoxidized acids.

Thus the carcinogens, by inhibiting peroxide formation, may produce conditions favourable for growth.

Precipitins to Grass Pollen Proteins

THE skin-reactive substances of grass pollen extracts used in clinical allergy have recently been shown to be proteins of average molecular weight 14,000[1]. Only two instances of a precipitating antiserum to grass pollen extracts are known[2,3].

In the present investigation, the isolated protein components themselves were employed in experiments with rabbits and guinea pigs, aluminium phosphate[4] and tubercle bacilli[5] being used as adjuvants. Precipitin formation occurred in six out of seven rabbits and in all five of the guinea pigs injected.

Phleum pratense (timothy grass) and *Dactylis glomerata* (cocksfoot or orchard grass) pollen proteins were used as the immunizing antigens in doses varying from 50 to 400 mgm. per animal over periods from five weeks to several months. Injections were given subcutaneously or intramuscularly. At an antiserum dilution-level of 1/4, optimum flocculation points were within the antigen-range of 0·01–0·004 gm. pollen protein/100 ml., ranges of 0·1–0·000001 gm./100 ml. being tested. These are maximum figures, since none of the antigens used can be regarded as pure. The testing antigens were crude and purified pollen extracts of *Phleum pratense*, *Dactylis glomerata*, *Festuca pratensis* (fescue) and *Cynodon dactylon* (Bermuda grass). All the antisera and antigens were cross-reacting; but the amount of precipitate formed appeared to depend upon the degree of botanical relationship between the grasses.

Timothy pollen proteins have been fractionated into active albumins and globulins[6]. The globulins only were found to precipitate readily with the antisera to the unfractionated complexes. Accordingly, the supernatants from these antigen–antibody complexes were active throughout the testing range when used for skin (prick) tests on allergic subjects. At the optimum flocculation point, the activity in the supernatant was most probably due to uncombined pollen–albumin. The antigen–antibody complexes were washed vigorously with cold sterile saline. Even after repeating the process six times, positive skin reactions were obtained with the floccules dissolved in the minimum of 0·1 *N* sodium hydroxide.

It seems thus, that in timothy at any rate, precipitin formation is due to at least one of the skin-reactive proteins.

Work is in progress to put the precipitin reactions on a quantitative basis, with the view of standardizing pollen extracts for clinical purposes in the treatment of asthma and hay fever.

A Source of Amniotic Fluid in the Lamb: the Naso-Pharyngeal and Buccal Cavities

INVESTIGATIONS in recent years have shown that there is an exchange of water between amniotic fluid and the blood streams of the mother and fœtus. This has been observed in the guinea pig[1] and human[2]. In the latter, a volume of water equal to about one-third the total volume of amniotic fluid is exchanged every hour from the twenty-eighth week to term[3]. At present, there is neither a set of observations nor a hypothesis to account for such a rapid and voluminous turnover of water, and no one has shown by what route or routes this fluid is derived.

During January to March 1953, extended observations in this laboratory were made on the reflex control of the circulation of the fœtal lamb. A total of twenty-eight fœtuses ranging in age from 110 days to term (149 days) were used. Most fœtuses survived from one to four hours. During an experiment, the fœtuses were delivered from ewes under 'Dial-urethane' anæsthesia by Cæsarean section. Breathing of the lamb was prevented, with the placental circulation maintained, by applying a rubber nose-bag (condom) over the head of the fœtus before it could breathe. This technique is like that used by Barcroft and Barron (see ref. 4), by Barclay, Franklin and Prichard[5] and others. Before the nose-bag was applied, a small amount of amniotic fluid was placed in it.
